# Calcium Carbonate Biomineralisation in Disparate Systems - Common Mechanisms? 

## Jennifer Katherine England

A thesis submitted for the degree of Doctor of Philosophy

Division of Earth Sciences, Centre for Geosciences, University of Glasgow

March 2005

#### Abstract

Biominerals are composite materials in which organic components control mineral nucleation and structure. Calcium minerals account for over $50 \%$ of biominerals, with calcium carbonate being the most common type.

This study considers the extent to which four calcium carbonate biomineral systems share common characteristics. Within the sample set, there is a range of ultrastructures and two types of calcium carbonate polymorph (calcite and aragonite). The mini survey includes three invertebrate systems: two members of the Phylum Brachiopoda; the articulated brachiopod Terebratulina retusa (Subphylum Rhynchonelliformea) and the inarticulated brachiopod Novocrania anomala (Subphylum Craniiformea), and a member of the Mollusca, the bivalve Mytilus edulis. The fourth, outlying vertebrate system, is the eggshell of the domestic fowl, Gallus gallus.

The minor element composition of each of the four systems is considered in the context of mineral ultrastructure. The shell of T. retusa comprises two layers; a primary layer of acicular calcite and an underlying secondary layer composed of calcite fibres. In thin section, a variation between the upper and lower portions of the secondary layer is evident. The concentration of magnesium, sulphur and strontium are significantly greater in the primary layer of the shell. Magnesium concentration also differs between the upper and lower regions of the secondary layer with higher concentration in the upper portion of the secondary layer.

The shell of $N$. anomala consists of two layers; a primary layer of acicular calcite and a secondary layer of calcite semi-nacre. N. anomala has a high magnesium calcite shell. The concentration of minor elements does not differ significantly between the primary and secondary layers.

Two calcium carbonate polymorphs occur in the M. edulis shell with an outer calcite layer and an inner aragonite layer. Magnesium concentration is higher in the calcite layer while strontium concentrations are greater in the aragonite layer. Sodium concentration gradually decreases across the calcite layer from the outer surface to the calcite/aragonite boundary and increases in the aragonite layer.

The eggshell of $G$. gallus contains shell membranes, mammillary caps, a palisade layer, a vertical crystal layer and an outer organic cuticle. The concentration of magnesium is high
in the mammillary caps, and decreases as the mammillary caps fuse and then gradually increases through the palisade and vertical crystal layers to the outer cuticle. The concentration of phosphorus and potassium is low in the mammillary caps and gradually increases through the shell to reach maximum concentration in the cuticle.

Variation in the concentration of minor elements in the shells of T. retusa and N. anomala do not relate to changes in mineral ultrastructure. Differences in shell chemistry between these two brachiopods may be related to differences in physiology. The principal control on the distribution of minor elements in M. edulis is crystal structure. In G. gallus the concentration of minor elements changes as ultrastructure changes. However, ultrastructure is unlikely to be the main control on shell chemistry, as abrupt changes in shell ultrastructure contrast to gradual changes in element distribution throughout the shell. While there may be similarities in the mechanisms controlling the minor element composition between some systems e.g. the extent to which some organisms control the ionic composition of the mineralising medium, there does not appear to be a common principal mechanism that governs the chemical composition of these four biominerals.

To some extent, more unity is evident in the biochemical characteristics of the organic matrix that are common to the four systems. The soluble organic matrices of the shells all contain small, acidic proteins. The amino acid composition of the four systems also displays some similarities such as a high glycine concentration. In each case, sulphated sugars are also associated with the soluble organic matrix.

Closer examination of the organic components reveals that the protein profiles are different in each of the four systems.

## Acknowledgments

I am extremely grateful to the Engineering and Physical Sciences Research Council for funding for this three year studentship (Grant number GR/R23107/01).

I would firstly like to thank Dr. Maggie Cusack for her help, support and guidance over the past three years and Dr. Martin Lee for his advice and encouragement. I am indebted to Sandra Tierney who has not only provided me with exceptional technical knowledge but has been a great friend. A special thankyou is required for Robert McDonald for his assistance with EPMA and SEM, Kenny Roberts for his help with IT, Bill Higgison for assistance with XRD and John Gilleece for preparation of samples. Many thanks to Eddie for driving myself and Big Dave to Oban to collect brachiopods. I am also grateful to the crew of the RV Calanus for their assistance with brachiopod collection and making me welcome on board. I would also like to thank Dr Rob Martin and Dr Paul Edwards from the Department of Physics, University of Strathclyde for their advice on CL spectroscopy.

I would like to thank the late Sir Alwyn Williams FRS, FRSE for his help and guidance with interpretation of brachiopod shell structure.

I am extremely grateful to all the postgraduates for keeping me sane, in particular to Sarah and Davie for being good friends over the last three years. A special thankyou goes to Liz Campbell for her friendship and enthusiasm for running 10 K races and to Big Dave for being a bad influence (RC now). Thanks also to Wolfie for being a great friend and listener.

Finally and most importantly I would like to thank my Mum, Dad and Bob for their love, support and encouragement.

## Declaration

The material presented in this thesis summarises the results of three years of independent research carried out in the Division of Earth Sciences, University of Glasgow. The research was supervised by Dr. Maggie Cusack (University of Glasgow) and Dr. Martin Lee (University of Glasgow).

This thesis is a result of my own research and any published or unpublished work of other researchers has been given full acknowledgment in the text.

## Chapter 1 Introduction

### 1.1 Introduction

Biominerals are produced by organisms from all five kingdoms (Lowenstam and Weiner, 1989). They vary in complexity from chains of magnetite crystals produced by magnetotactic bacteria to the intricate structures of bone, tooth enamel and dentine. Biominerals perform a wide range of functions from magnetic sensors to protection and motion. Calcium minerals account for approximately $50 \%$ of biogenic minerals (Lowenstam and Weiner, 1989), of which calcium carbonate is the common phase and is frequently present as one or both of the polymorphs of $\mathrm{CaCO}_{3}$, calcite and aragonite.

Biominerals are composite materials composed of a mineral phase with an organic matrix. Biomineralisation processes can be considered in two categories: Biologically Induced Mineralisation and Biologically Controlled Mineralisation (Lowenstam and Weiner, 1989). Biologically induced mineralisation takes place by precipitation of minerals commonly from metabolic and cellular processes (Lowenstam and Weiner, 1989 and Mann, 2001). In this case, the organism does not regulate the formation of the biomineral. Biologically controlled mineralisation refers to the interaction of organic macromolecules and ions to regulate the precipitation and growth of the mineral (Lowenstam and Weiner, 1989 and Mann, 1990 and 2001). The products of biologically controlled mineralisation display exquisite morphologies and have physical properties that differ from those of inorganic carbonates (Feng et al., 2000 and Magdans and Gies, 2004).

### 1.2 Biominerals

Biominerals comprise a mineral phase with an organic matrix of proteins, carbohydrates and lipids. The protein component controls the nucleation, morphology and crystal structure of the mineral (Lowenstam and Weiner, 1989, Belcher et al., 1996 and Falini et al., 1996). The minor and trace element compositions of the skeletons of marine invertebrates have been of interest due to their potential application as seawater palaeothermometers (e.g. Elderfield and Ganssen, 2000 and Martin et al., 2002). The chemical composition of the mineral and the organic matrix can also provide information on the mechanisms that underlie the formation of biominerals. The following sections describe some of the extensive literature on the composition of both the inorganic and organic components of biominerals. For a more detailed review of minor element
composition and organic matrix composition of biominerals refer to Sections 3.2 and 4.2 respectively.

### 1.2.1 Inorganic Components

The concentration and spatial distribution of minor and trace elements within the skeletons of marine invertebrates is determined by a range of biological and environmental variables (Lorens and Bender, 1977, Dodd, 1965 and Elderfield et al., 1996). $\mathrm{Mg} / \mathrm{Ca}$ values of calcite skeletons of a variety of marine invertebrates display a positive correlation with the temperature of ambient seawater (Lea et al., 1999, Lowenstam, 1961 and Dickson, 2002). However, this relationship is not consistent between species and biological factors may influence the incorporation of magnesium into marine invertebrate skeletons (Vander Putten et al., 2000 and Lorens and Bender, 1977). $\mathrm{Mg} / \mathrm{Ca}$ values in shells of M. edulis do not display a consistent correlation with water temperature over the year (Vander Putten et al., 2000). Although the influence of temperature is not dismissed, other factors must therefore contribute to controlling the incorporation of magnesium into M. edulis calcite (Vander Putten et al., 2000). One suggestion is that variations in growth rates may contribute to variation in element distribution throughout individual $\mathrm{CaCO}_{3}$ shells. Buening and Carlson (1992) identified two patterns of magnesium distribution in the shells of the articulated brachiopods Terebratulina unguicula and Terebratalia transversa. Both ontogenetic patterns of magnesium distribution are attributed to variations in growth rate through ontogeny and seasonal variations in the availability of nutrients (Buening and Carlson, 1992). In some cases it is difficult to ascertain the precise controls on incorporation of magnesium into marine biominerals as temperature and growth rate are partially coupled (Mii and Grossman, 1994) and may also influence physiological processes that ultimately control the uptake of magnesium into the shells of some taxa (Nurnberg et al., 1996).
$\mathrm{Mg} / \mathrm{Ca}$ values also influence crystal morphology (Meldrum and Hyde, 2001), while varying the concentration of magnesium alters the kinetics of calcite growth in vitro (Hincke \& St Maurice, 1998). Magnesium may therefore have an active role in the development of the biomineral.

Strontium/calcium values of biotic carbonate may be related to a number of factors including temperature, growth rate and the organism's physiology (Stoll et al., 2002,

Vander Putten, 2000, Stecher III et al., 1996, Klein et al., 1996). A positive relationship between strontium concentration and temperature has been found in the aragonite test of the benthic foram, Hoeglundina elegans (Reichart et al., 2003). There is also a positive relationship between strontium concentration and temperature in the calcite tests of the benthic foraminifera, Cibicides wuellerstorfi and Cibicides refulgens (Rathburn and De Deckker, 1997). However, this relationship is not consistent with other species of benthic foraminifera (Rathburn and De Deckker, 1997). Strontium concentration in abiotic and biotic marine carbonate may also be related to precipitation rate (Lorens, 1981; Carpenter and Lohmann, 1992), the concentration of magnesium present in the crystal lattice (Mucci and Morse, 1983) and the concentration of strontium in the seawater (Lorens and Bender, 1980; Hockett et al., 1997).

### 1.2.2 Organic Components

The organic components of biominerals are extremely important to many aspects of biomineral formation, influencing the nucleation, crystal structure and morphology of the mineral (Lowenstam and Weiner, 1989, Simkiss and Wilbur, 1989, Mann, 2001, Belcher et al., 1996, Wheeler and Sikes, 1984). The organic matrix can be divided into two fractions, the intercrystalline matrix, which surrounds the mineral, and the intracrystalline matrix, which is encased within the mineral. Demineralisation of the biomineral using the calcium chelator, ethylene diamine tetra acetic acid (EDTA) releases the intracrystalline matrix which comprises two fractions: an insoluble and a soluble organic matrix fraction.

The insoluble matrix is composed of hydrophobic macromolecules, which provide a framework for crystal formation and influence the final properties of the biomineral (Feng et al., 2000, Weiner et al., 1983, Weiner, 1984). The concentration of insoluble organic matrix varies considerably between species and in some cases is absent, suggesting that the framework proteins do not have an essential role in the mineralisation of some skeletons (Weiner et al., 1983).

In contrast, the soluble organic matrix is present in all biologically controlled systems (Weiner et al., 1983). It is composed predominantly of acidic macromolecules that have a calcium binding function, which is essential to the nucleation process (Weiner, 1979). A number of soluble matrix proteins are also glycosylated and the carbohydrate groups may
be involved in the biomineralisation process possibly via their sulphate and carboxylic acid groups (Cusack et al., 2000, Ameye et al., 2001, Mann, 2001).

There have been a number of in vitro studies on the effect of organic matrix proteins on calcium carbonate crystal growth (e.g. Feng et al. 2000b, Zaremba et al. 1996, Wheeler et al. 1981 and Levi et al., 1998). Soluble matrix proteins exert control over both crystal morphology and polymorph (Belcher et al., 1996, Thompson et al., 2000, Levi et al., 1998 and Falini et al., 1996). Aragonite grew in the presence of macromolecules extracted from the aragonite layers of molluscs which were adsorbed onto a substrate of $\beta$-chitin and silkfibroin (Falini et al., 1996). By contrast, calcite formed with the addition of macromolecules extracted from the calcite layers of the same molluscs. A mixture of proteins extracted from mollusc shell nacre on addition to $\mathrm{CaCO}_{3}$ induced the formation of aragonite in vitro in the absence of a preformed organic matrix (Belcher et al., 1996).

### 1.2.3 Biomineralisation Mechanisms

The general model for the structure of organic matrices comprises a core framework of hydrophobic macromolecules with surface layers of hydrophilic proteins and polysaccharides (Weiner, 1984). This model is illustrated in the nacreous layer of mollusc shells, in which the surface of a core framework comprising the polysaccharide $\beta$-chitin and layers of silk-fibroin-like protein is covered by acidic macromolecules (Weiner and Traub, 1984). Levi-Kalisman et al., (2001) confirmed the presence of ordered interlamellar sheets of organic matrix between layers of nacre in the bivalve Atrina. However, the overall structure of the layer is determined by $\beta$-chitin, while the other constituent of the organic matrix, silk-fibroin, is not an essential component of the interlamellar sheets (Levi-Kalisman et al., 2001).

The nucleation, morphology and crystal structure of biominerals is controlled by the interaction of organic molecules and ions at the surface of the crystal nucleus (Mann, 1988, 2001). This match of charge, polarity and stereochemistry between organic molecules and ions, termed "molecular recognition", reduces the activation energy required for crystal nucleation (Mann, 1988, 2001).
lonotropy involves the accumulation of binding sites in localised areas which result in regions of high charge density (Mann, 2001). The accumulation of ionic charge attracts a
large number of ions resulting in the nucleation of the biomineral (Mann, 1988, 2001). With respect to calcium carbonate, the binding sites fixed to the organic matrix framework bind $\mathrm{Ca}^{2+}$ ions, which attract carbonate anions $\left(\mathrm{CO}_{3}{ }^{2-}\right)$. In turn, the carbonate anions attract $\mathrm{Ca}^{2+}$ ions. Nucleation takes place due to the local supersaturation of ions resulting in an amorphous mineral deposit (Greenfield et al., 1984). Amorphous calcium carbonate deposits have been identified as a precursor stage to crystalline deposits in some invertebrate calcium carbonate skeletons, including calcite sea urchin spicules (Beniash et al., 1997, Wilt et al., 2003), spicules from ascidian skeleton (Aizenberg et al., 2002) and the aragonitic larval shells of the bivalves Mercenaria mercenaria and Crassostrea gigas (Weiss et al., 2002).

The alternative model to ionotropy, the template model (epitaxy) requires that the structural arrangement of the surface of the organic matrix matches that of the structure of the crystal face (Mann, 1988). The soluble organic matrices of the molluscs, Crassostrea virginica, Mercenaria mercenaria, Crassostrea irredecens and Nautilus pompilius contain a high concentration of the amino acids glycine and aspartic acid suggesting the presence of proteins with repeat sequences of (Asp-Y) $n$ where $Y$ is glycine or serine (Weiner and hood, 1975). If this sequence is present in the $\beta$-sheet formation then the arrangement of aspartic acid residues would correspond to the crystallographic arrangement of $\mathrm{Ca}^{2+}$ in the aragonite lattice (Weiner and Hood, 1975).

This model does not explain the preferential formation of calcite or aragonite owing to the similarities in crystal structure of the (001) faces of calcite and aragonite, it has been suggested that the polymorph may be dependant on the arrangement of $\mathrm{CO}_{3}{ }^{2-}$ anions around $\mathrm{Ca}^{2+}$ ions (Mann, 1988 and 2001).

### 1.3 Emergence and Early Evolution of Biominerals

The relatively sudden emergence of organisms with complex mineralised skeletons together with a radiation of metazoans with complex body plans in the Early Cambrian (545-595Ma) marks one of the major events in the evolution of life. Only a few shelly fossils have been found at the base of the Cambrian but there followed a gradual proliferation of taxa with mineralised skeletons (Knoll, 2003). The abundance of shelly fossils increased over 25 Ma from the base of the Cambrian (Knoll, 2003). A number of theories have been suggested for the apparently rapid development of skeletal
mineralisation. These have included environmental factors, such as rising atmospheric oxygen levels (Towe, 1970), and biological factors including an increase in predation pressure (Bengtson, 1994, Simkiss, 1989).

There is no clear evidence to indicate that the evolution of marine animals with mineralised skeletons in the Early Cambrian was principally linked to environmental changes. The diversification of taxa producing mineralised skeletons may have resulted from a combination of biological and environmental factors. Many of the cell mechanisms involved in producing biominerals were present before the appearance of skeletal material in the fossil record (Simkiss, 1989). These cell systems and biochemical pathways that were established before the evolution of eukaryotes predisposed cells to producing biominerals. These cell mechanisms, coupled with the development of complex multicellular organisms and the environmental stresses (i.e. increased predation) that were prevalent in the Early Cambrian, led to the diversification of taxa with skeletons (Simkiss, 1989).

There are some biochemical similarities between the organic matrices of organisms from different phyla, in particular the presence of acidic proteins (Weiner et al., 1983). This suggests that there may be common processes involved in the formation of biominerals (Weiner et al., 1983). Biologically controlled mineralisation could therefore have originated in common Early Precambrian ancestors or evolved following the divergence of phyla (Lowenstam and Weiner, 1983). While phylogenetic evidence indicates that skeletons evolved independently in the Metazoa (Knoll, 2003), the biochemical mechanisms that underlie skeletal formation may have a common origin (Westbroek and Marin, 1998).

### 1.4 Aims of this Study

In order to establish whether organisms from different phyla employ similar processes in the formation of biominerals it is necessary to establish whether the organic matrix and mineral components of the biominerals share common characteristics. While some comparative studies have been undertaken, few of these have compared organisms from different phyla e.g. Weiner et al., (1983). The aims of this study are to compare the organic and inorganic constituents of biominerals produced by organisms from different
phyla and so determine whether they share common mineralisation components and by implication processes.

As calcium carbonate is the most common biomineral, four calcium carbonate systems from three different phyla were used for the survey. The four systems comprise biominerals produced by three invertebrates and a vertebrate. The invertebrates include two members of the phylum Brachiopoda; the articulated brachiopod Terebratulina retusa (Sub-phylum Rynchonelliformea) and the inarticulated brachiopod Novocrania anomala (Sub-phylum Craniata), and a member of the phylum Mollusca (Class Bivalvia); Mytilus edulis. The vertebrate system is the eggshell of the domestic fowl, Gallus gallus. These four systems comprise two calcium carbonate polymorphs, calcite and aragonite, and a variety of ultrastructures.

The concentration and distribution of minor elements within each is described within the context of ultrastructure in Chapter 3. Chapter 4 compares the organic matrix composition, in particular the protein composition of the four systems in terms of protein molecular weight and charge, amino acid composition and the presence of sulphated sugars.

### 1.5 The Four Biomineral Systems

The following sections provide a brief introduction to the four systems analysed in this study. For a more detailed description of the ultrastructure of the shells of T. retusa, $N$. anomala, M. edulis and G. gallus refer to Chapter 3, Sections 3.3.1 to 3.3.4 inclusive.

### 1.5.1 Terebratulina retusa

Terebratulina retusa (Figure 1.1) is an articulated brachiopod belonging to the Subphylum Rhynchonelliformea, Class Rhynchonellata (Williams et al., 1996). The Subphylum Rhynchonelliformea is characterised by an organocarbonate shell with a fibrous secondary layer. Rhynchonelliform brachiopods possess a pedicle. The calcite shell comprises two layers; an outer primary layer of acicular calcite and an inner secondary layer of calcite fibres (Figure 3.1), both of which are secreted by the mantle epithelium (Williams, 1968). Specimens of $T$. retusa attached to shells of the bivalve Modiolus modiolus were collected from a depth 200 m in the Firth of Lorne, NW Scotland.

Figure 1.1 Specimen of the articulated brachiopod Terebratulina retusa collected from the Firth of Lorne, NW Scotland

Anterior to posterior shell length is approximately 2 cm .

### 1.5.2 Novocrania anomala

Novocrania anomala (Figure 1.2) is an inarticulated brachiopod belonging to the Subphylum Craniiformea, Class Craniida (Williams et al., 1996). The Subphylum Craniiformea is characterised by an organocarbonate shell with a laminar secondary layer lacking teeth and sockets. In contrast to members of the Rhynchonelliformea such as $T$. retusa, Craniiformea lack a pedicle. In N. anomala, the ventral valve is cemented to the substrate. Specimens of N. anomala were collected from the same location as T. retusa.

Figure 1.2 Dorsal valve of a specimen of the inarticulated brachiopod Novocrania anomala

The width of the dorsal valve is approximately 1.5 cm .

### 1.5.3 Mytilus edulis

Mytilus edulis (Figure 1.3) belongs to the Phylum Mollusca, Class Bivalvia, Subclass Pteriomorphia. The bivalve molluscs have soft parts enclosed within an equivalved shell, while the Ptreiomorphia encompass a group of byssate bivalves with shells composed of either calcite, aragonite, or both calcium carbonate polymorphs. Mytilus edulis has a shell with an outer layer of prismatic calcite and an inner aragonite layer. In bivalve molluscs the shell is separated from the mantle by the extrapallial fluid from which calcium carbonate crystallisation takes place (Simkiss and Wilbur, 1989). The inorganic composition of the extrapallial fluid is regulated by the movement of ions across the mantle and is different to seawater (Simkiss and Wilbur, 1989 and Crenshaw, 1972). Specimens of M. edulis were obtained from a mussel farm on the coast of Oban, NW Scotland.

Figure 1.3 Interior of specimen of the Bivalve Mollusc Mytilus edulis

Length of the shell from anterior to posterior is approximately 7 cm .

### 1.5.4 Avian Eggshell (Gallus gallus)

The calcite eggshell of the domestic fowl, Gallus gallus comprises six regions; the inner and outer shell membranes, the calcified mammillary caps, the pallisade layer, the vertical crystal layer and the cuticle which is composed of organic material and hydroxyapatite crystals (Dennis et al., 1996 and Fernendez et al., 2001). The egg is produced in the isthmus and uterine sections of the hen oviduct (Nys et al., 1999). The membranes that encompass the yolk and albumen of the egg are produced in the isthmus, which forms the distal part of the oviduct. As the egg moves down the oviduct, initial calcification takes place in the red isthmus where the mammillary caps are formed. A large proportion of calcite deposition and the addition of the eggshell cuticle finally take place in the uterus (Nys et al., 1999, Fernandez et al., 2001 and Solomon, 1991). Eggshell formation is rapid being complete within 24 hours in a constant temperature environment (Simkiss, 1961 and Cusack et al., 2003). Specimens of the eggshell of G. gallus were obtained from a commercial source.

Chapter 1 Introduction

Figure 1.4 (a) Eggshell formation in the domestic fowl Gallus gallus (after Gautron, 1994), (b) Cross-section of the eggshell of G. gallus

MC mammillary caps, $P$ palisade layer, VC vertical crystal layer, C cuticle.

## 2 Materials and Methods

### 2.1 Materials (Appendix A)

### 2.2 Sample Collection and Preparation

Living specimens of Terebratulina retusa and Novocrania anomala were collected from the Firth of Lorne, Oban, NW Scotland ( $56^{\circ} 24 \mathrm{~N}, 5^{\circ} 384^{\prime}$ W). Samples were obtained from a depth of 200 m by dredging, which was carried out by the crew of the research vessel Calanus from the Dunstaffnage Marine Laboratory, Oban. Specimens were stored in seawater and transported to the University of Glasgow. Specimens of the bivalve Mytilus edulis were collected from a mussel farm on the coast of Oban. Eggshells were obtained from a commercial source.
T. retusa is attached to the substrate via a muscular pedicle. The pedicle was removed, the valves disarticulated and the soft tissues removed using dental tools. In contrast, the ventral valve of $N$. anomala is cemented to the substrate. When removing the ventral valve from the substrate it is therefore difficult to ensure that the base of the valve is not contaminated by substrate material. As a result, only the dorsal valve of $N$. anomala was analysed. The dorsal valve was separated from the ventral valve and the soft tissues removed. T. retusa and $N$. anomala valves were cleaned in an aqueous solution of sodium hypochlorite ( $1 \% \mathrm{v} / \mathrm{v}$ ) and rinsed in Milli $\mathrm{Q}^{\mathrm{TM}}$ water.

For M. edulis, the left and right valves were prised apart, the soft tissues removed and the valves cleaned in a solution of sodium hypochlorite ( $1 \% \mathrm{v} / \mathrm{v}$ ). The thick periostracum was removed using a hand drill equipped with a grinding wheel tool. The valves were rinsed in Milli $Q^{\text {TM }}$ water.

To extract extrapallial fluid from specimens of $M$. edulis the shell valves were prised apart and a syringe inserted between the mantle tissues and the shell. To prevent contamination by seawater only live specimens with the mantle tissues fully attached to the inner surface of the shell were used. The fluid was extracted, washed with sodium phosphate buffer and concentrated through Microcon filters under centrifugation at $3000 \mathrm{rpm}(734.53 \mathrm{~g}$ ) for 15 minutes.

For the three marine invertebrates, only shells obtained from individuals that were alive when collected were analysed.

The eggshells were halved and the contents removed. The membrane covering the inner surface of the shell was removed by incubation in an aqueous solution of sodium hypochlorite ( $37 \% \mathrm{v} / \mathrm{v}$ ) for 20 minutes (Cusack and Fraser, 2002). All specimens were rinsed thoroughly with Milli $Q^{\mathrm{TM}}$ water.

### 2.3 X-ray Diffraction (XRD)

X-ray diffraction (XRD) utilises the reflection profile of X-rays from crystal lattice planes for mineral identification. Each mineral has a unique XRD profile (i.e. d spacing and $2 \theta$ angle) enabling mineral identification by comparison of the XRD profile with those in the Joint Committee on Powder Diffraction Standards (JCPDS) database.

Each sample was powdered in an agate mortar and pestle and mixed with acetone. The powder was pasted onto a glass slide, allowed to dry and loaded on to A Philips PW 1050/35 X-ray diffractometer.

### 2.4 Examination of Shell Ultrastructure

Samples were prepared as described in Section 2.2. The shells were fractured and mounted on scanning electron microscope stubs. The samples were gold coated and the fractured edges examined using secondary electrons in a Cambridge Instruments S360 Scanning Electron Microscope (SEM) operated at 20 kV .

### 2.5 Thin Section Preparation

Samples were prepared as described in Section 2.2. The samples were embedded in araldite resin and sectioned. T. retusa and N. anomala valves were sectioned from anterior to posterior, M. edulis shells were sectioned at $90^{\circ}$ to the hinge axis, and a square section (approximately $1 \mathrm{~cm}^{2}$ ) from the equator of the eggshell was cut in half. The samples were fixed to glass slides, ground to a thickness of $30 \mu \mathrm{~m}$ and polished using diamond compounds $(6 \mu \mathrm{~m}-1 / 4 \mu \mathrm{~m})$ for reflected light microscopy and cathodoluminescence microscopy and spectroscopy.

### 2.6 Minor and Trace Element Analysis

### 2.6.1 Sample Preparation

Samples were prepared as described in Section 2.2, however the M. edulis periostracum and the eggshell membrane were not removed for element analysis. T. retusa and $N$. anomala valves were sectioned from anterior to posterior, M. edulis shells were sectioned at $90^{\circ}$ to the hinge axis, and a square section (approximately $1 \mathrm{~cm}^{2}$ ) was taken from the equator of the eggshell. All samples were embedded in araldite resin blocks, polished with diamond compounds ( $6 \mu \mathrm{~m}$ to $1 / 4 \mu \mathrm{~m}$ ) and carbon coated for electron microprobe spot analysis (EMPA) and element mapping by wavelength dispersive spectral analysis (WDS). Element mapping was also carried out using a Cambridge Instruments SEM equipped with an energy dispersive spectrometer (EDS).

### 2.6.2 Electron microprobe analysis (EPMA)

Electron microprobe analysis (EPMA) enables the concentration of minor and trace elements in a polished sample to be quantified. The wavelength dispersive spectrometer (WDS) provides better peak resolution and a lower detection limit than EDS for quantitative analysis of elements that are present in low concentrations. A further advantage of EPMA in relation to other chemical analysis techniques (e.g. atomic absorption) is that micrometre-sized volumes of samples can be analysed.

Analyses in a line perpendicular to the line of section were carried out using a Cameca SX50 Electron Microprobe equipped with three wavelength dispersive spectrometers. The instrument was operated at 15 KV with a 10 nA current and the spot was defocused to $10 \mu \mathrm{~m}$ in order to prevent beam damage. The electron microprobe was calibrated using standards for $\mathrm{Na}, \mathrm{Mg}, \mathrm{S}, \mathrm{K}, \mathrm{Ca}, \mathrm{Mn}, \mathrm{Fe}$ and Sr (see Appendix B for calibration standards). Three specimens of T. retusa, N. anomala, M. edulis and G. gallus were analysed and each analysis repeated in triplicate. Matrix corrections were carried out using a PAP correction procedure. The detection limit for each element on the SX50 electron microprobe was calculated from:

Detection limit $=\frac{3}{m} \sqrt{\frac{\mathrm{Rb}}{\mathrm{Tb}}}$

Where
$\mathrm{m}=$ counts/second/\% element in the standard
$\mathrm{Rb}=$ counts per second on the background
$\mathrm{Tb}=$ count time on the background
Data errors were calculated from:

$$
\% \text { Error }=\frac{100}{\sqrt{T}(\sqrt{R p}-\sqrt{R b})}
$$

Where
$\mathrm{T}=$ count time on the peak
$\mathrm{Rp}=$ counts per second on the peak
$\mathrm{Rb}=$ counts per second on the background
The quantitative analysis of carbonates by EPMA can be problematic, especially for elements that are present in low concentration (e.g. Mn). Thus, it is essential to determine both the detection limit of the electron microprobe for each element and the errors related to the data set.

A plot of Na concentration as a function of the percentage error associated with the data is presented in Figure 2.1. The errors shown are calculated for analyses carried out on $N$. anomala under electron microprobe conditions of 15 kV with a 10 nA defocused beam. There is a clear relationship between the concentration of each element in the sample and the size of the error associated with each data point. Error size is greatest for those elements that are present in low concentration. For sodium analyses, a large proportion of the data falls within a $+/-5-10 \%$ error limit and is above the detection limit of $0.089 \mathrm{wt} \%$. For magnesium, the error limit is below $+/-2 \%$ while errors for Sr data are commonly between $+/-10-15 \%$. For analyses of manganese, the data set is unreliable as the errors associated with the data are large and elemental concentration is below the calculated detection limit of $0.055 \mathrm{wt} \%$. Other elements that are present in concentrations below the detection limit of the electron microprobe include iron and, in some instances, potassium
and phosphorus. Plots of $\mathrm{Mg}, \mathrm{S}, \mathrm{Ca}, \mathrm{Sr}, \mathrm{Mn}, \mathrm{Fe}, \mathrm{P}$ and K were produced for each system and only elements that are above the detection limit are discussed.

Figure 2.1 Plot of concentration of Na against percentage error for $N$. anomala electron microprobe analyses

The detection limit and errors for sodium were calculated using the equation presented in Section 2.6.2. The errors on the data set for sodium concentration in N . anomala were calculated using the equations in Section 2.6.2. The detection limit of $0.08 w t \%$ is shown as a dashed line.

### 2.6.3 Element Mapping

EDS element mapping is a qualitative technique that produces an image showing spatial variations in element concentrations. Elemental maps were produced using a Cambridge instruments S360 SEM equipped with an Oxford Instruments Isis Microanalysis System, (operated at 15 KeV with a 4 nA current). In instances where an element was present in particularly low concentration or a more detailed map was required, element mapping was carried out using the Cameca SX50 electron microprobe operated at 15 KV with a 20 nA current and a $5 \mu \mathrm{~m}$ defocused beam.

### 2.6.4 Cathodoluminescence (CL) Microscopy

The wavelength and intensity of light emitted from a sample when bombarded by electrons can be characteristic of the mineral type and the elements incorporated within it. CL imaging has an advantage over electron probe analysis and EDS mapping because it may reveal the presence of elements in concentrations below analytical detection. CL images of the systems were produced using a CITL Technosyn 8200 MK4 operated at 25 kV and mounted on a Zeiss Axioplan petrological microscope.

### 2.6.5 Cathodoluminescence (CL) Spectroscopy

CL-spectroscopy can be used to determine the presence of certain chemical elements from their CL emission wavelength (Habermann et al., 1999). In cases where an element is below the detection limit for microprobe analyses, the high sensitivity of CL-spectroscopy is an advantage (Habermann, 2002).

Thin sections were prepared as described in Section 2.5. CL spot analyses and CL mapping were carried out using a Cameca SX100 electron microprobe equipped with a CL spectrometer capable of determining the wavelength and intensity of CL emission over the wavelength range of $350-850 \mathrm{~nm}$. CL maps and spectra were displayed using the computer software, Cathodoluminescence Hyperspectral Imaging and Manipulation Program (CHIMP).

### 2.7 Determination of Total Organic Concentration and Distribution

### 2.7.1 Loss on Ignition

Loss on ignition was employed to determine the total organic content of each of the four biominerals. Each sample was powdered, weighed and heated in an oven at $500^{\circ} \mathrm{C}$ for two hours then re-weighed. The weight loss following combustion corresponds to the mass of organic material originally present.

### 2.7.2 Scanning Electron Microscope Backscatter (BSE) Imaging

Backscatter electron (BSE) imaging in the SEM can be used to highlight spatial variations in mean atomic number. Here BSE imaging has been used in an attempt to determine the distribution of organic material within the four biomineral systems. The significant difference in mean atomic number between calcium carbonate and organic components of the shell should enable these two components to be distinguished. BSE images were produced using a Cambridge Instruments S360 SEM operated at 15 KV with a range of beam currents.

### 2.8 Extraction, purification and visualisation of shell protein

### 2.8.1 Extraction of intercrystalline protein

Shell samples were crushed to a fine powder using a Temer rock crusher (for large quantities) or a ceramic mortar and pestle (for smaller quantities). Powdered samples were incubated in an aqueous solution of guanidine hydrochloride (GnHCL) containing proteinase inhibitors and Tris buffer ( 4 M guanidine, 50 mM Tris, 2.5 mM Benzamidine$\mathrm{HCl}, 50 \mathrm{mM}$ N-ethylmaleimide, 1 mM Phenyl methyl sulphonyl fluoride), buffered to pH 7.4 under constant agitation for 24 hours. The insoluble fraction was separated from the soluble fraction by centrifugation at $4000 \mathrm{rpm}(3452 \mathrm{~g})$ for 15 minutes. Guanidine incubation and centrifugation were repeated for the remaining sample. The supernatants were pooled and stored at $3^{\circ} \mathrm{C}$.

### 2.8.2 Extraction of intracrystalline protein

The remaining sample was incubated in ethylene diamine tetra acetic acid (EDTA), with proteinase inhibitors ( $20 \%$ EDTA, 50 mM Tris, 2.5 mM Benzamidine-HCL, 50 mM Nethylmaleimide, 1 mM Phenyl methyl sulphonyl fluoride), buffered to pH 7.4 under constant agitation for up to 5 days. The insoluble fraction was removed by centrifugation at $4000 \mathrm{rpm}(3452 \mathrm{~g})$ for 15 minutes and the supernatant stored at $3^{\circ} \mathrm{C}$.

### 2.8.3 Purification of intercrystalline and intracrystalline protein

The supernatant obtained from both the intercrystalline and intracrystalline fractions was concentrated and residual GnHCl and EDTA removed by filtration through a Minitan ${ }^{\mathrm{TM}}$ tangential flow ultrafiltration system (Cusack et al., 1992). Both fractions were filtered using 10 kDa cut off filters. Both samples were further concentrated through Centriprep ${ }^{\mathrm{TM}}$ concentrators with 10 kDa cut off filters under centrifugation at $3000 \mathrm{rpm}(1942 \mathrm{~g})$ for 20 minutes, and through Microcon filters also with 10 kDa filters under centrifugation at $10,000 \mathrm{rpm}(8161.4 \mathrm{~g})$ for 15 minutes.

### 2.8.4 Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS

 PAGE)Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS PAGE) involves the separation of proteins based entirely on their molecular weight. One-dimensional discontinuous SDS PAGE was used to analyse the proteins from the four biomineral systems using a modification of the method described by Schägger and Von Jagow (1987).

Acrylamide is crosslinked by the compound $\mathrm{N}, \mathrm{N}^{\prime}$-methylene-bis-acrylamide (Bisacrylamide) producing a mesh that acts as a "molecular sieve". The pore size of the gel mesh is controlled by the concentration of both acrylamide and Bis-acrylamide. Polymerisation is initiated by ammonium persulphate (APS) and catalysed by the addition of Tetramethylethane (TEMED). Fifteen percent polyacrylamide gels were prepared as described in Table 2.1. In some instances $20 \%$ gels were used in order to improve the resolution of low molecular weight proteins. Stacking gels were prepared as described in Table 2.1.

| Reagent | Resolving Gel <br> $(15 \%)$ | Resolving Gel <br> $(20 \%)$ | Stacking Gel |
| :---: | :---: | :---: | :---: |
| Acrylamide/Bis | 3.6 ml | 4.8 ml | 0.42 ml |
| Gel Buffer | 3.3 ml | 3.3 ml | 1 ml |
| Glycerol | 1 ml | 1 ml | $\mathrm{n} / \mathrm{a}$ |
| Milli Q | 2.1 ml | 0.9 ml | 2.53 ml |
| APS | $75 \mu \mathrm{l}$ | $75 \mu \mathrm{l}$ | $40 \mu \mathrm{l}$ |
| TEMED | $7.5 \mu \mathrm{l}$ | $7.5 \mu \mathrm{l}$ | $7.5 \mu \mathrm{l}$ |

Table 2.1 Solution composition for $\mathbf{2 0 \%}$, $\mathbf{1 5 \%}$ gels and stacking gels for SDS PAGE

For each sample, the concentrated protein mixture was heated with sample buffer (Tris buffer ( 50 mM ), SDS ( $4 \% \mathrm{w} / \mathrm{v}$ ), Glycerol ( $12 \% \mathrm{w} / \mathrm{v}$ ), $\beta$-Mercaptoethanol ( $2 \% \mathrm{w} / \mathrm{v}$ ), Bromophenol blue $(0.0002 \% \mathrm{w} / \mathrm{v})$ at $100^{\circ} \mathrm{C}$ for 4 minutes. Sodium dodecyl sulphate is a denaturing detergent that binds to proteins in a ratio of 1.4 g SDS per gram polypeptide (Andrews, 1986). The charge on the polypeptide is overcome by the large negative charge on the SDS resulting in a constant charge to mass ratio. Protein separation through the gel is therefore based solely on protein size.

The molecular weights of proteins of known molecular weight (standards) are presented in Table 2.2. The volume of sample buffer mixture loaded onto the gel differed according to the protein concentration within the sample, which was estimated from UV spectroscopy using $A_{280 \mathrm{~nm}}$ of 1.0 for $1 \mathrm{mg} / \mathrm{mL}$ protein. For $15 \%$ gels, a voltage of 60 V was applied across the gel for three hours, the same voltage was applied for five hours to $20 \%$ gels.

| Unstained Proteins | Full Range (M.wt) Proteins | Low M.wt ProteinsProteins |
| :---: | :---: | :---: |
| 66 | 250 | 44 |
| 45 | 160 | 29 |
| 36 | 105 | 20 |
| 29 | 75 | 14 |
| 24 | 50 | 5 |
| 20 | 35 | 2 |
| 14 | 30 |  |
|  | 25 |  |
|  | 15 |  |
|  | 10 |  |

Table 2.2 Molecular weight (M. wt) of proteins of known molecular weight (standards) used for SDS PAGE (expressed in kDa)

The molecular weights of the unknown proteins are determined from a calibration curve of the electrophoretic mobility ( Rf ) as a function of the $\log$ molecular weight of the proteins of known molecular weight (Figure 2.4).

Figure 2.2 Calibration curve of electrophoretic mobility as a function of the log molecular weight of proteins of known molecular weight

Proteins of known molecular weight (unstained protein standards) prepared as described in Section 2.8.4 and electrophoresed in a 15\% polyacrylamide gel as described in Section 2.8.4

### 2.8.5 Coomassie Brilliant Blue Staining

Proteins were fixed and revealed by staining overnight in a solution of Coomassie Brilliant Blue (Coomassie Brilliant Blue ( $0.5 \% \mathrm{w} / \mathrm{v}$ ), methanol ( $30 \% \mathrm{v} / \mathrm{v}$ ) and acetic acid ( $10 \%$ $\mathrm{v} / \mathrm{v}$ )). Gels were then incubated in destain solution (methanol ( $30 \% \mathrm{v} / \mathrm{v}$ ) and acetic acid ( $10 \% \mathrm{v} / \mathrm{v})$ ) to remove background staining.

### 2.8.6 Silver Staining

Silver staining provides a more sensitive staining technique than Coomassie Blue staining and is able to detect around 1 lng of protein (Hames and Rickwood, 1990). Following staining with Coomassie Blue, the gels were rinsed in Milli $Q^{T M}$ water for 30 minutes and incubated in DTE solution ( $0.0005 \% \mathrm{w} / \mathrm{v}$ ) for 30 minutes followed by silver solution ( $0.2 \%$ $\mathrm{w} / \mathrm{v})$ for 30 minutes. Gels were agitated in developer solution $\left(\mathrm{Na}_{2} \mathrm{CO}_{3} .10 \mathrm{H}(0.8 \% \mathrm{w} / \mathrm{v})\right.$, formaldehyde $(0.05 \% \mathrm{v} / \mathrm{v}))$ until staining took place. To stop staining, gels were incubated in an aqueous solution of acetic acid ( $1 \% \mathrm{v} / \mathrm{v}$ ) for 10 minutes.

### 2.8.7 Acridine Orange Staining

Acridine orange can be used to detect sulphated macromolecules e.g. sulphated sugars in polyacrylamide gels. The staining protocol was carried out as described by Dauphin et al., (2003a). Gels were incubated in a fixing solution of methanol ( $40 \%$ ) and acetic acid ( $10 \%$ ) for 30 minutes, followed by a stain solution of Acridine orange ( $0.02 \%$ ) in a solution of $5 \%$ methanol for 30 minutes. Gels were rinsed in Milli $Q^{T M}$ water and destained in a solution of $25 \%$ ethanol and $7 \%$ acetic acid.

### 2.8.8 Isoelectric Focusing

Isoelectric focusing can be used to separate proteins based on their overall charges. The method is similar to gel electrophoresis in that a gel medium is used to separate the protein components of the sample. For isoelectric focusing the gel contains ampholytes, which are necessary to establish a pH gradient across the gel. By applying a voltage across the gel the amphyolytes migrate to either the anode or the cathode depending on whether they are
acidic or basic. The point at which they stop is dependant on their pI value i.e. the pH at which they are neutral.

Isoelectric focusing (IEF) was undertaken in the Biology Department, University of York. Gels were prepared in accordance with Table 2.3. Isoelectric focusing (IEF) was carried out using a Biorad III IEF cell. The standards and samples were loaded on to the gel using a guide. Two sets of standards were used, a broad range set of standards ( $\mathrm{pH} 3-10$ ) and a low range set of standards $(\mathrm{pH} 2.5-6.5)$. Six samples were loaded onto the gel (mussel aragonite, mussel calcite, eggshell, total mussel, T. retusa and $N$. anomala EDTA extracts). An initial voltage of 100 V was applied for 15 minutes to set up a pH gradient across the gel. The voltage was increased to 200 V for 15 minutes and finally 450 V for one hour. On application of a voltage across the gel the proteins migrate towards the point where the pH is equal to their pI (i.e. protein net charge $=0$ ). The gel was then washed with a fixer solution (17.3g Sulphosalicylic acid, 57.5 g Trichloroacetic acid (TCA)) for 30 minutes, stained with a solution of Coomassie Brilliant Blue ( 0.92 g Coomassie Brilliant Blue $/ 800 \mathrm{ml}$ destain solution) and placed in a destain solution ( 500 ml ethanol and 160 ml acetic acid). The protein samples were compared to the protein standards with known isoelectric points.

| Reagent | Concentration |
| :---: | :---: |
| Ampholine | 0.5 ml |
| Glycerol | 0.5 ml |
| Acrylamide | 1.35 ml |
| Water | 7.65 ml |
| Ammonium persulphate (APS) | $42 \mu \mathrm{l}$ |
| Tetramethylethane (TEMED) | $7 \mu \mathrm{l}$ |

Table 2.3 Solution composition for IEF gels

### 2.9 Amino Acid Analysis

Amino acid analysis provided a comparison between the amino acid compositions of organic matrix proteins within the four systems. Before amino acid analysis can be carried out, the peptide bonds that link individual amino acids must be hydrolysed. In this case, manual vapour phase hydrolysis was used.

### 2.9.1 Manual Hydrolysis

Shell samples were cleaned as described in Section 2.2, powdered and weighed. To determine the intracrystalline amino acid composition, samples were powdered, weighed and incubated in an aqueous solution of sodium hypochlorite $(1 \% \mathrm{v} / \mathrm{v})$ for one hour. These samples were washed thoroughly with MilliQ ${ }^{\mathrm{TM}}$ water until no bleach could be detected by smell. All samples were dissolved in an aqueous solution of $\mathrm{HCl}(2 \mathrm{~N})$, transferred to hydrolysis tubes and vacuum dried. The hydrolysis tubes were placed in hydrolysis vials containing $500 \mu \mathrm{l} \mathrm{HCl}(6 \mathrm{~N})$, purged with argon for 60 seconds and then sealed. Vials were heated at $165^{\circ} \mathrm{C}$ for one hour. The heated vials were vented in a fume cupboard to release the acid vapour and left to cool. Samples were then reconstituted in $\mathrm{K}_{3}$ EDTA.

### 2.9.2 Amino Acid Analysis

The Applied Biosystems 420 Amino Acid Analyser employs the first stage of the Edman degradation sequence (described in Section 2.10.2) for derivatization. The free amino acids resulting from hydrolysis are tagged with phenylisothiocyanate (PITC) to produce phenylthiocarbamyl-amino acids (PTC-AA). This increases detection of the amino acids by UV absorbance at a wavelength of 254 nm . In the case of the 420 A Amino Acid analyser, the derivatization process is automated.

### 2.9.3 Summary of Steps for Amino Acid Analysis

The samples in aqueous solution are applied to glass frits. The derivatisation jaw clamps to each frit, individually delivering an aliquot of methanol containing $K_{3}$ EDTA. This step prevents any metal contamination that may interfere with the derivatisation process. Diisopropylethylamine (DIEA) vapour is delivered to the sample in order to neutralise any acid. PITC is delivered to the frit and derivatization takes place resulting in the production of PTC-AAs. The PTC-AAs are transferred to the transfer flask by aqueous buffer where they are mixed. The contents of the flask is delivered to the Model 130A for hplc separation of the derivatised amino acids.

### 2.10 N -terminal Sequencing

### 2.10.1 Transfer of Protein to ProBlott Membrane

Electroblotting enables the direct transfer of proteins from a polyacrylamide gel to a Polyvinylidine fluoride membrane (ProBlott membrane) for N -terminal sequencing. To transfer the proteins from the gel to a ProBlott membrane the gel was incubated in transfer buffer (CAPS buffer ( $10 \mathrm{mM}, \mathrm{pH} 11$, methanol $(10 \% \mathrm{v} / \mathrm{v})$ ) for five minutes. The ProBlott membrane was dipped in methanol and rinsed in transfer buffer. The proteins were transferred using a BioRad Mini Transblot Electrophoretic Transfer Cell. A voltage of 55 V was applied across the cell for one hour.

The Problott membrane was rinsed in Milli $Q^{T M}$ water, dipped in methanol and placed in Coomassie Blue stain solution (Coomassie Brilliant Blue-R ( $0.5 \% \mathrm{w} / \mathrm{v}$ ), methanol (30\% $\mathrm{v} / \mathrm{v})$, and acetic acid ( $10 \% \mathrm{v} / \mathrm{v}$ ) ) for one minute. The membrane was then destained by rinsing in $50 \%$ methanol and allowed to dry.

### 2.10.2 $N$-terminal Sequencing

N-terminal sequencing was carried out using an Applied Biosystems Procise Edman Protein Sequencer at the University of Edinburgh, Proteomics Centre. This automated sequencer employs Edman Degradation Chemistry for protein sequencing (Figure 2.5). The Edman reagent, phenylisothiocyanate (PITC), reacts with the N -terminal amino acid to produce a phenythiocarbamyl derivative. Breakage of the peptide bond between the first and second amino acid results in the formation of a phenylhiodantoin derivative of the first amino acid. The phenylthiohydantoin derivative is then identified by high performance liquid chromatography (hplc). This process is repeated for the subsequent amino acids to determine the N -terminal protein sequence.

Figure 2.3 Edman degradation chemistry (from Murray et al., 2000)

### 2.11 Calcium Carbonate Crystal Growth

### 2.11.1 Kitano Protocol

Calcite crystals were grown according to the Kitano Protocol (Kitano, 1962). Glassware was washed in hot soapy water, followed by $0.1 \%(\mathrm{v} / \mathrm{v}) \mathrm{HCl}$ and rinsed with methanol. Between each stage, the glassware was rinsed with Milli $Q^{\mathrm{TM}}$ water. The reaction solution consisting of $2 \mathrm{~g} \mathrm{CaCO}_{3} /$ litre Milli $Q^{\mathrm{TM}}$ water, was prepared in a 51 round bottomed flask and stirred rapidly. $\mathrm{CO}_{2}$ gas was bubbled through the reaction solution for $11 / 2$ hours. The solution was filtered through two filter papers into a conical flask to remove any residue, and $\mathrm{CO}_{2}$ gas bubbled through for a further 30 minutes. In order to determine the optimum conditions for calcite growth, saturated calcium hydrogen carbonate solution was distributed in a well plate and the crystals left to develop under a range crystallisation times (24.48, and 72 hours).

### 2.11.2 Calcite Grown in the Presence of Protein Extract

Calcite crystals were grown in the presence of intracrystalline proteins that had been extracted from the four biomineral systems (Sections 2.8.1-2.8.3). Sodium phosphate buffer was removed from the intracrystalline/extrapallial fluid extracts by washing with Milli $Q^{T M}$ water through Microcon ${ }^{\text {TM }}$ filters. In order to determine the influence of intracrystalline/extrapallial fluid proteins on crystal growth in vitro, protein extracts were added to the saturated calcium hydrogen carbonate solution. The effect of sodium phosphate buffer on calcite growth was also determined by addition of $2 \mu \mathrm{l}$ of buffer to the calcium hydrogen carbonate solution.

A one centimetre diameter coverslip was placed in each well of a 25 well plate and covered with 1 ml of saturated calcium hydrogen carbonate solution. Protein extracts were added to each well. The concentration of each extract was dependant on the availability of intracrystalline/extrapallial fluid protein extracts (Table 2.4). The coverslips were removed after a period of 24 and 48 hours.

| Sample | Volume of Protein <br> Solution Added | Final Protein <br> Concentration in 1mI <br> reaction volume $(\mu \mathrm{g} / \mathrm{ml})$ |
| :---: | :---: | :---: |
| T. retusa | $2 \mu \mathrm{l}$ of $0.8 \mu \mathrm{~g} / \mu \mathrm{l}$ | 1.6 |
| $N$. anomala | $2 \mu \mathrm{l}$ of $7.4 \mu \mathrm{~g} / \mu \mathrm{l}$ | 14.8 |
| $M$. edulis | $2 \mu \mathrm{l}$ of $8.8 \mu \mathrm{~g} / \mu \mathrm{l}$ | 17.6 |
| Extrapallial Fluid | $2 \mu \mathrm{l}$ of $1.6 \mu \mathrm{~g} / \mu \mathrm{l}$ | 3.2 |
| Eggshell | $2 \mu \mathrm{l}$ of $0.8 \mu \mathrm{~g} / \mu \mathrm{l}$ | 1.6 |

Table 2.4 Concentration of protein added to crystal growth solution

The coverslips were air dried, attached to SEM stubs and gold-coated in order to examine crystal morphology using the SEM. The mineralogy was determined by X-ray diffraction using a Phillips PW 1050/35 X-ray diffractometer. The number and size of crystals in SEM images was determined using the computer software, Scion Image.

## 3.Ultrastructure and Minor and Trace Element <br> Concentration

### 3.1 Introduction

Chemical analysis of modern and fossil carbonate shells is an important tool for both developing our knowledge of the processes involved in the formation of biominerals and increasing our understanding of evolutionary relationships between biomineral systems. By determining the chemical composition of various biomineral systems and the effect of elements on the growth and structure of the biomineral we can begin to understand some of the processes involved in carbonate biomineralisation. The question is complicated however due to the influence of a wide range of mineralogical, biological and environmental factors on the chemical composition of calcium carbonate biominerals.

This chapter provides a detailed account of the crystal ultrastructure of T. retusa, N. anomala, M. edulis and the avian eggshell (Gallus gallus) in relation to the distribution and concentration of minor and trace elements throughout each shell. The four systems described here display a range of crystal ultrastructures and two types of calcium carbonate polymorph since the shell of $M$. edulis contains both calcite and aragonite. They have also been subjected to a range of environmental conditions during formation. The two brachiopods $T$. retusa and $N$. anomala were obtained from the same location and therefore have experienced the same water depth and temperature conditions. M. edulis is commonly found in shallow coastal zones with warmer, higher salinity seawater conditions than those from which the two brachiopods were obtained. In contrast to the three marine systems the eggshell forms within a regulated, constant temperature environment. By analysing systems that comprise various forms of calcium carbonate with a range of ultrastructural motifs, it is possible to assess the range of variations in chemical composition or the extent to which chemical composition is constant despite differences in structure.

The minor and trace element composition of each system was analysed quantitatively by electron probe. Three sets of spot analyses were carried out in a line perpendicular to the line of section for samples of each system. The data is presented both as line analyses across each shell and as scatter plots in order to determine if there are any relationships
between the concentrations of various elements within each system. Qualitative maps of element distribution in each system were produced by SEM. For some samples where more detailed elemental maps were required the maps were made using the electron probe. As discussed in Section 3.2.3 cathodoluminescence can provide valuable information on the presence of certain chemical elements. Therefore all four systems were analysed by optical cathodoluminescence and cathodoluminescence spectroscopy.

### 3.2 Previous Work

The skeletons of marine invertebrates are commonly composed of calcium carbonate, as either or both of the polymorphs, calcite and aragonite. The chemical composition of these skeletons has been of much interest due to the information that skeletal chemistry provides about the processes involved in biomineral formation. The use of shell chemistry to determine seawater palaeotemperatures has also been extensively investigated (Elderfield and Ganssen, 2000, Martin et al. 2002, Eggins et al., 2003 and Parkinson et al., 2005). As there are a number of biological and environmental factors that affect shell chemistry (e.g. temperature, growth rate and the composition of the mineralising medium), it is a complex task to determine the exact controls on the chemical composition of any one individual organism.

### 3.2.1 Magnesium

Temperature is thought to be one of the main controls on the incorporation of magnesium in biogenic calcium carbonate (Mii and Grossman, 1994 and Dodd, 1967) and a positive relationship between seawater temperature and the concentration of magnesium in the calcium carbonate exoskeletons of a range of marine invertebrates has been identified (Lowenstam, 1961, Lea et al., 1999 and Dickson, 2002). The magnesium/calcium ratio of calcium carbonate skeletons has frequently been employed as seawater thermometer and palaeothermometer (Watanabe et al. 2001, Lear et al., 2002 and Lear et al., 2000). It is therefore important to establish if the temperature-related partitioning of magnesium is consistent between species.

Foraminifera are both geographically widespread and biologically less complex than the Brachiopoda or the Bivalvia and have been of particular interest in determining the controls on calcification and the uptake of minor and trace elements. A positive
exponential relationship between magnesium and temperature has been described for both benthic and planktonic foraminifera (Rosenthal et al.1997, Nurnberg et al. 1996 and Lea et al. 1999), and a number of studies have attempted to use this relationship to determine past seawater temperatures (Martin et al., 2002, Elderfield and Ganssen, 2000 and Lear et al., 2000). The positive correlation between water temperatures and magnesium concentrations has also been described for the carbonate skeletons of more complex taxa. Lowenstam (1961) identified an increase in the magnesium content of recent brachiopod shells with increasing water temperatures, while Mii and Grossman (1994) also found evidence for a positive trend between magnesium and temperature in a well preserved fossil specimen of Neospirifer. A positive relationship between temperature and magnesium content has also been found in some species of echinoderm (Dickson, 2002).

The relationship between temperature and the magnesium concentration of carbonates is however complicated by a number of physical factors including the effect of salinity (Dodd, 1967) and the effect of the size and charge of the magnesium ion on lattice partitioning in different $\mathrm{CaCO}_{3}$ polymorphs (Rosenberg, 1990), and also biological factors such as the organism's rate of growth throughout ontogeny (Buening and Carlson, 1992). Seawater chemistry alone cannot explain the magnesium content of marine carbonate skeletons as many organisms have skeletons whose magnesium content differs from that predicted from distribution coefficients. In particular, brachiopods live in habitats where fluctuations in seawater chemistry are insufficient to account for measured variations in shell chemistry (Mii and Grossman, 1994). The eggshell of the domestic fowl, Gallus gallus is precipitated in a constant temperature environment and so if temperature were the sole control on partitioning, magnesium concentration should be constant throughout the eggshell. However the concentration of magnesium varies through the eggshell, which suggests that it is not a simple relationship between the $\mathrm{Mg} / \mathrm{Ca}$ ratio and temperature, while other factors may also be involved in controlling the magnesium content of the eggshell (Cusack et al., 2003).

Incorporation of magnesium ions into the calcite mineral lattice inhibits crystal growth (Davis et al., 2000, de Leeuw, 2002 and Wilbur and Bernhardt, 1984). Many organisms exhibit $\mathrm{Mg} / \mathrm{Ca}$ ratios that are different to values predicted from the composition of the seawater within which the organism lived (Rosenberg, 1990). It has been suggested that many organisms employ mechanisms for controlling the uptake of magnesium from seawater, thus limiting the inhibiting effect of magnesium. Lorens and Bender (1977,
1980) identified a physiological mechanism in the mussel M. edulis, which allows the organism to exclude magnesium from the extrapallial fluid. Tests of the planktonic foraminifera Globigerinoides sacculifer are undersaturated with magnesium with respect to predicted values (Nurnberg et al., 1996). They suggest that foraminifera are therefore capable of controlling their uptake of magnesium to some extent. However the physiological processes that ultimately control the uptake of magnesium are temperature controlled.
$\mathrm{Mg} / \mathrm{Ca}$ ratio may determine the polymorph of calcium carbonate and influence the morphology of the crystals that are formed (Meldrum and Hyde., 2001, Kitamura, 2001, Loste et al., 2003). Evidence from in vitro studies suggests that the precipitation of aragonite and high magnesium calcite is favoured by the presence of $\mathrm{Mg}^{\mathbf{2 +}}$ (Kitano and Hood, 1965). Alternations in the $\mathrm{Mg} / \mathrm{Ca}$ ratio of seawater caused by fluctuations in the spreading rate of midocean ridges may have resulted in the transition between calcite and aragonite seas through the Palaeozoic (Hardie, 1996, Stanley et al., 2002). Stanley et al., (2002) suggest that simple marine invertebrates which precipitate aragonite or high magnesium calcite skeletons in the modern aragonite sea may in fact have produced low magnesium calcite skeletons in past calcite seas when the $\mathrm{Mg} / \mathrm{Ca}$ ratio of the seawater was low. The simple relationship between the $\mathrm{Mg} / \mathrm{Ca}$ ratio of the fluid and the resulting mineralogy of abiotic calcium carbonate has however, been questioned (Given and Wilkinson, 1985), while Blackwelder et al., (1976) found that in the case of the coccoliths of the coccolithophorid Cricosphaera cartarae the calcium carbonate polymorph produced is not solely dependent on the concentration of magnesium in solution.

### 3.2.2 Strontium

Within abiotic calcium carbonate systems, the concentration of strontium within calcite may relate to the precipitation rate of the mineral, where an increase in the distribution coefficient of strontium occurs with increased precipitation rate (Lorens, 1981, Major and Wilber, 1991). An increase in precipitation rate also leads to an increase in the strontium content of biotic calcite (Lea et al., 1999). A positive relationship between the calcification rate and the concentration of strontium within calcite tests of benthic foraminifera has been identified (Lea et al., 1999, Rathburn and De Deckker, 1997 and Elderfield et al., 1996). If the incorporation of strontium into the tests of benthic foraminifera is kinetically controlled then the composition of the test may be indirectly
linked to factors such as temperature and water depth/ $/ \mathrm{CO}_{2}$ levels which influence the rate of calcification (Elderfield et al., 1996). The controls on strontium incorporation into aragonite may be different than those associated with strontium incorporation in calcite.

The potential application of $\mathrm{Sr} / \mathrm{Ca}$ ratios in the calcium carbonate skeletons of marine invertebrates as environmental indicators has gained much attention (Stoll et al., 2002, Vander Putten, 2000 and Stecher III et al., 1996). Strontium thermometry is based on the inverse relationship between water temperature and the $\mathrm{Sr} / \mathrm{Ca}$ ratio of aragonitic coral skeletons (Beck et al., 1992 and Weber, 1973). A correlation between strontium concentration and water temperature has also been identified in other species. Reichart et al., (2003) identified a positive correlation between water temperature and the concentration of strontium in the tests of Hogelundina elegans. Stecher III et al., (1996) suggested that the $\mathrm{Sr} / \mathrm{Ca}$ ratio in the aragonite layers of the shells of two molluscs, Mercenaria mercenaria and Spisula solidissima is kinetically controlled, as low $\mathrm{Sr} / \mathrm{Ca}$ ratios in the shells of both molluscs correlate with periods of slow growth.

The influence of precipitation rate on the $\mathrm{Sr} / \mathrm{Ca}$ ratio of some calcite biomineral systems has been questioned. Klein et al. (1996) found that the $\mathrm{Sr} / \mathrm{Ca}$ ratio of the bivalve mollusc Mytilus trossulus (Mytilus edulis) is primarily controlled by the metabolic activity of the mantle and secondarily by salinity, while the shell growth rate had little effect on the strontium concentrations. Lorens and Bender (1980) also found no evidence of a relationship between $\mathrm{Sr} / \mathrm{Ca}$ ratio and growth rate in the shell of Mytilus edulis but found that the $\mathrm{Sr} / \mathrm{Ca}$ ratio in both the calcite and aragonite layers of the bivalve shell varied linearly with the $\mathrm{Sr} / \mathrm{Ca}$ ratio in artificial seawater solutions in which the mussels were grown. Hockett et al., (1997) also found a linear relationship between the incorporation of strontium into the calcium carbonate shells of barnacles and the concentration of strontium in artificial seawater. In comparison Vander Putten et al., (2000) found that the variations in $\mathrm{Sr} / \mathrm{Ca}$ ratios found in the calcite layer of specimens of $M$. edulis could not be explained simply in terms of the ratio of $\mathrm{Sr} / \mathrm{Ca}$ in solution, while they also found no evidence for a correlation between $\mathrm{Sr} / \mathrm{Ca}$ and temperature.

### 3.2.3 Cathodoluminescence

Cathodolminescence (CL) is the emission of photons from a material due to bombardment with electrons. In geosciences, cathodoluminescence is commonly used for analysing the
texture and chemical composition of rock samples. Certain chemical elements act as luminescence activators (e.g. Mn), while others act as luminescence quenchers (e.g. Fe). The wavelength of the light emitted is dependent on both the activator element and the identity of the mineral in which it is present. Manganese is the most common activator in carbonates, while $\mathrm{Fe}^{2+}$ is the main quencher (Marshall, 1988). The colour of luminescence produced in the presence of manganese differs between calcite and aragonite. In calcite Mn produces an orange-red luminescence while aragonite luminesces green (Sommer, 1972). The intensity of luminescence also varies with the concentration of the activator element, although the concentration of manganese that is needed to activate luminescence in calcite is poorly known. For biogenic carbonate, Richter and Zinkernagel (1981) found that a minimum manganese concentration of $20-40 \mathrm{ppm}$ is necessary for visible cathodoluminescence, while Mason and Mariano (1990) suggest that the activation concentration may be as low as 10 ppm . Habermann et al., (1998) suggest that caution is required as a sample may still emit luminescence which is not visibly detectable even with very low Mn concentrations.

In palaeontology, cathodoluminescence has principally been used to assess the extent of diagenesis in fossil samples (Samtleben et al., 2001, Popp et al., 1986). It had been previously thought that recent biogenic carbonates do not luminesce and thus fossils that luminesce have been diagenetically altered. However, recent work has shown that modern carbonate skeletons also luminesce and the potential application of cathodoluminescence for the study of recent carbonate shells has been recognised (Barbin, 1991).

Many carbonate shells comprise growth increments between which the chemical composition varies (Lowenstam, 1961, Dodd, 1967, Rosenberg and Hughes, 1991, Barbin, 1992). Luminescence emission may therefore reflect these variations where the concentration of activator elements is above the detection limit (Barbin, 1992). Barbin et al., (1991) detected cathodoluminescence in a range of marine and freshwater organisms. In most cases, manganese was the principal activator and the colour of luminescence produced was related to the mineral in which it occurred. Orange luminescence was detected from the calcite layers of the molluscs, Pecten maximus, Ostrea edulis and Mytilus edulis. The aragonite layers within P. maximus and M. edulis were nonluminescent while faint green CL bands were apparent in Ostrea edulis.

Cathodoluminescence spectroscopy quantifies the information recorded by optical CL. The spectrum produced provides information on the intensity and wavelength of CL that is emitted. CL-spectroscopy is a relatively new method for analysis of biogenic carbonates and, as such, the data available for various species is limited. Barbin et al., (1995a) report the CL spectrum determined from the cephalopod Nautilus pompilus in which an emission band resulting from manganese substitution in aragonite is present at 540 nm and a band related to intrinsic emission is present within the blue range of the spectrum. For the cephalopod Nautilus macromphalus, the main emission was in the blue range of the spectrum.

### 3.3 Results

### 3.3.1 Terebratulina retusa Ultrastructure and Minor Elements

### 3.3.1.1 Ultrastructure

The Terebratulina retusa shell has three layers; an outer organic periostracum, underlain by a primary layer of acicular calcite and an inner secondary layer composed of calcite fibres (Figure 3.1). The primary layer is approximately $25 \mu \mathrm{~m}$ thick and has a sharp boundary with the fibrous secondary layer, which is $350 \mu \mathrm{~m}$ thick. The interlocking fibres of the secondary layer show blunt terminations as illustrated in Figures 3.2 and 3.3.

Transmitted light images of thin sections of T. retusa are presented in Figures 3.4 and 3.5. The primary and secondary layers of the shell are distinct in both plane polarised light (PPL) (Figure 3.4) and cross-polarised light (XPL) (Figure 3.5), with punctae extending through both the primary and secondary layers (Figure 3.4). Both images indicate that the secondary layer has two distinct regions, which are not resolved in SEM images (Figures 3.1 and 3.2).

Figure 3.1 Secondary electron image of the primary (PL) and secondary (SL) layers of Terebratulina retusa

SEM image of a fractured cross section of a specimen of T . retusa. The outer part of the shell, the primary layer (PL) is to the top of the image.

Figure 3.2 Secondary electron image of the primary (PL) and secondary (SL) layers of Terebratulina retusa

SEM image of a fractured cross section of a specimen of T . retusa. The image shows the blunt terminations of the secondary layer fibres.

Figure 3.3 Secondary electron image of the secondary layer fibres of Terebratulina retusa

SEM image of a specimen of T. retusa illustrating the blunt terminations of the secondary layer fibres.

Figure 3.4 Plane-polarised transmitted light image of Terebratulina retusa in thin section

The primary layer (PL) is distinct from the secondary layer (SL). A division between the upper (SL1) and lower (SL2) regions of the secondary layer is also apparent.

Figure 3.5 Cross-polarised light image of Terebratulina retusa in thin section

The primary layer (PL) is distinct from the secondary layer (SL). A division between the upper (SL1) and lower (SL2) regions of the secondary layer is also apparent.

### 3.3.1.2 Minor Element Composition-Electron Microprobe Analysis

Electron microprobe analyses of magnesium, sulphur, strontium and sodium across the primary and secondary layers of three specimens of $T$. retusa are presented in Figure 3.6 (a-c). Magnesium, sulphur, strontium and sodium are all above the limit of detection. For T. retusa, manganese, iron, potassium and phosphorus are below the limit of detection and are therefore not discussed. As some elements may be present in different phases within the shell e.g. magnesium $\left(\mathrm{MgCO}_{3}\right)$ in the crystalline phase and sulphur within the organic matrix, data are expressed as $w t \%$ element (carbonate weight percentage data is provided in the Appendix). Results are summarised in Table 3.1.

| Specimen | Layer | Mg Conc. <br> Range <br> $(\mathbf{w t \%})$ | Sr Conc. <br> Range <br> (wt\%) | Na Conc. <br> Range <br> (wt\%) | S Conc. <br> Range <br> (wt\%) | Figure <br> No. |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| a | Primary | $0.99-1.54$ | $0.12-0.15$ | $0.16-0.17$ | $0.26-0.30$ | 3.6 a |
| a | Secondary | $0.15-0.89$ | $0.08-0.16$ | $0.10-0.16$ | $0.13-0.33$ | 3.6 a |
| b | Primary | $0.28-0.75$ | $0.13-0.15$ | $0.16-0.16$ | $0.21-0.33$ | 3.6 b |
| b | Secondary | $0.12-0.34$ | $0.08-0.16$ | $0.11-0.18$ | $0.10-0.24$ | 3.6 b |
| c | Primary | $0.26-0.70$ | $0.11-0.16$ | $0.19-0.21$ | $0.21-0.31$ | 3.6 c |
| c | Secondary | $0.17-0.47$ | $0.08-0.14$ | $0.16-0.19$ | $0.15-0.23$ | 3.6 c |

## Table 3.1 Summary of electron microprobe results for T. retusa

The results displayed in Table 3.1 summarise the concentration range (i.e. the lowest concentration to the highest concentration) of $\mathrm{Mg}, \mathrm{Sr}, \mathrm{Na}$ and S in the primary and secondary layers of T . retusa.

The boundary between the primary and secondary layers of $T$. retusa is marked by distinct changes in shell chemistry. The concentration of magnesium is greater in the primary layer of $T$. retusa than the secondary layer. Magnesium reaches a maximum of 1.54, 0.75 and $0.70 \mathrm{wt} \%$ respectively in the primary layers of specimens $\mathrm{a}, \mathrm{b}$ and c (Figure 3.6a-c and Table 3.1). In all cases there is an abrupt decrease in magnesium concentration across the primary/secondary layer boundary. Within the secondary layer there is some variation in the distribution of magnesium between samples. Data for the specimen a displays an abrupt increase in magnesium concentration in the upper secondary layer (SL1), i.e. around
$100 \mu \mathrm{~m}$ into the secondary layer (Figure 3.6a), which is not present in the other two specimens. Specimen $b$ contains a greater concentration of magnesium in the upper region of the secondary layer (SL1) compared to the lower region of the secondary layer (SL2) (Figure 3.6b). All three samples exhibit an increase in magnesium concentration at the innermost shell surface, albeit poorly defined for the sample in Figure 3.6(b).

Sulphur and strontium also display a similar pattern of higher concentrations in the primary layer in comparison to the secondary layer. Sulphur attains a maximum concentration of $0.3 \mathrm{wt} \%$ in the primary layer of each of the three specimens (Figure 3.6a-c and Table 3.1). Strontium reaches a maximum concentration of $0.16 \mathrm{wt} \%$ in the three specimens (Figure 3.6a-c and Table 3.1). Sodium attains a maximum concentration of $0.17 \mathrm{wt} \%$ in specimen $a, 0.18 w t \%$ in specimen $b$ and $0.21 w t \%$ in specimen $c$ (Figure 3.6a-c and Table 3.1).

One-way ANOVA was carried out on nine sets of analyses from three specimens of $T$. retusa in order to determine if there is a significant difference in the concentration of all four elements between the primary and secondary layers. Figure 3.7 (a-e) presents boxplots of element concentration as a function of the shell layer. Each box represents the inter-quartile range of the data set, while the mean value is displayed as a red circle. The concentration of magnesium ( P value 0.001 ), sulphur ( P value 0.000 ), calcium ( P value 0.018 ) and strontium ( $P$ value 0.002 ) varies significantly between the two shell layers. Sodium concentration ( P value 0.228 ) is not significantly different between the primary and secondary layers.

Figure 3.6 (a, b \& c) Electron microprobe spot analyses across three specimens of Terebratulina retusa

Electron microprobe analyses were carried out as described in Section 2.6.2. Elements displayed are above their limit of detection. The y axis of graph (a) is on a different scale to the $y$ axes of graphs $b$ and $c$ due to variations in overall element concentrations between individuals.

## Figure 3.7 ( $\Omega-\mathrm{e}$ ) Boxplots of element concentration in the primary and secondary layers of $T$. retusa

The mean element concentration values for the primary and secondary layers for nine sets of analyses from three specimens of $T$. retusa were analysed using ANOVA to determine if there is a significant difference in element concentration between the primary and secondary layers of the shell. Each box represents the interquartile range (IQR) of the sample set (i.e. Q1-Q3). Top and bottom whiskers extend from the box to the highest and lowest values within Q1+1.5*IQR.. Values outlying the range of the whiskers are marked as stars (*). Mean values are displayed as red circles.

The distribution of elements in T. retusa (Figure 3.6) implies that there is a positive correlation between magnesium, sodium and sulphur concentration. Scatter plots of element concentration in the primary and secondary layers of T. retusa are presented in Figures 3.8 (a-j). Each graph contains data from ten sets of analyses taken across the primary and secondary layers of three specimens of $T$. retusa. Pearson correlation coefficients are shown in Table 3.2.

In the primary and secondary layers the correlation coefficient between sulphur and magnesium is similar. There is a positive correlation between sulphur and strontium, sulphur and sodium and between strontium and sodium in both layers of the shell however the positive trend is stronger in the primary layer in each case. There is a weak negative correlation between calcium and magnesium in the primary and secondary layers, and between calcium and sulphur in the secondary layer.

| T. retusa | Primary Layer |  | Secondary Layer |  |
| :---: | :---: | :---: | :---: | :---: |

| $\mathbf{C a} / \mathbf{S r}$ | 0.311 | 0.122 | 0.066 | 0.312 |
| $\mathbf{S r} / \mathbf{N a}$ | 0.759 | 0.000 | 0.367 | 0.000 |

Table 3.2. Pearson correlation coefficients with P-values for element concentration in the primary and secondary layers of $T$. retusa

Pearson correlation coefficients were calculated to determine the linear relationships between element concentrations in the primary and secondary layers of T. retusa. Values close to $I$ indicate a strong positive linear correlation.

Figure 3.8 (a-j) Scatter plots of element concentration in the primary and secondary layers of Terebratulina retusa
The concentration of minor elements in the primary and secondary layers of three specimens of T . retusa was analysed by electron microprobe as described in Section 2.6.2. The data from three sets of electron microprobe analyses from each specimen are plotted in order to determine any relationships between elements present within the shell.

Figure 3.9 (a-d) presents X-ray maps of magnesium, sulphur, sodium and strontium in a specimen of T. retusa. X-ray maps of magnesium, sulphur and calcium distribution produced using the electron probe are presented in Figure 3.10 (a-c). The difference in magnesium and sulphur concentration between the primary and secondary layers is illustrated in Figures 3.9 a and b and 3.10 a and b . These maps clearly indicate that there is a higher concentration of magnesium and sulphur in the primary layer of the shell. The maps also display related regions of high concentration of magnesium and sulphur, which extend from the primary layer into the secondary layer. Figure 3.10 (c) indicates that the same regions of the shell, which have a high magnesium and sulphur content, are depleted in calcium.

Figure 3.9 (a-d) X-ray maps of element concentration in Terebratulina retusa acquired by SEM
a. Mgka, b. Sk, c. Nak , d. Srk . For each map light grey areas indicate a greater element concentration while dark grey areas indicate lower element concentration.

Chapter 3 Ultrastructure and Minor and Trace Element Composition

a. Magnesium, b. Sulphur, c. Calcium. For each map, light grey areas indicate a greater element concentration while dark grey areas indicate lower element concentration.

### 3.3.1.3 Cathodoluminescence Spectroscopy

T. retusa is optically non-luminescent but luminesces blue when studied by CLspectroscopy (Figure 3.11a and b). Both the wavelength and intensity of luminescence is consistent across the shell (Figure 3.11a). Dark blue/black areas of the map are areas of the sample that have been damaged by the electron probe.

Figure 3.11(a) Hyperspectral image showing the intensity and wavelength of CL emission from a specimen of Terebratulina retusa, (b) CL emission spectrum acquired from Terebratulina retusa

CL spectroscopy was carried out as described in Section 2.6.5. The image and spectrum were produced using the software, CHIMP. The red cross in Figure 3.11(a) marks the point from which the spectrum was obtained. Units on the $Y$ axis of the CL spectrum (Figure 3.11b) are arbitrary.

### 3.3.2 Novocrania anomala Ultrastructure and Minor Elements

### 3.3.2.1 Ultrastructure

The $N$. anomala shell has three layers; an outer organic periostracum, a primary layer consisting of acicular calcite and a secondary layer composed of calcite semi nacre (Figure 3.12). The shell also contains punctae (Figure 3.13), which branch at the terminus (Williams and Wright, 1970). The primary layer of the shell is composed of needle-like crystals, each of which is orientated at $45^{\circ}$ to the isochronous surfaces within the primary layer (Williams and Wright, 1970). The secondary layer is formed from calcite seminacre. Semi-nacre exhibits a laminar structure similar to that of aragonite nacre, which is characteristic of molluse shells. However semi-nacre differs in that it is composed of calcite rather than aragonite and has fewer screw dislocations (Weedon and Taylor, 1995). Steps form on the lattice surface due to dislocation of the lattice planes, the steps rotate producing a spiral growth pattern resulting in the formation of both left and right screw dislocations (Figure 3.14).

A transmitted light (plane polarised light) image is presented in Figures 3.15, in which the boundary between the primary and secondary layer and the laminar structure of the secondary layer are evident.

Figure 3.15 Transmitted light image of Novocrania anomala in thin section

The primary layer (PL), secondary layer (SL) and punctae $(P)$ are evident in thin section.

### 3.3.2.2 Minor Element Composition-Electron Microprobe Analysis

Electron microprobe analyses of magnesium, strontium, sodium and sulphur across the shells of three individuals of $N$. anomala are presented in Figure 3.16. Manganese, iron, potassium and phosphorus were all below the limit of detection of the SX 50 electron microprobe and are therefore not discussed. Results are summarised in Table 3.3.

| Specimen | Layer | Mg Conc. <br> Range <br> (wt\%) | Sr Conc. <br> Range <br> (wt\%) | Na Conc. <br> Range <br> (wt\%) | S Conc. <br> Range <br> (wt\%) | Figure <br> No. |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| a | Primary | $2.09-2.76$ | $0.21-0.22$ | $0.20-0.28$ | $0.28-0.31$ | 3.16 a |
| $\mathbf{a}$ | Secondary | $1.90-2.65$ | $0.18-0.25$ | $0.15-0.23$ | $0.25-0.44$ | 3.16 a |
| $\mathbf{b}$ | Primary | $1.90-2.36$ | $0.26-0.28$ | $0.14-0.17$ | $0.31-0.32$ | 3.16 b |
| $\mathbf{b}$ | Secondary | $1.09-3.73$ | $0.13-0.33$ | $0.08-0.23$ | $0.21-0.34$ | 3.16 b |
| $\mathbf{c}$ | Primary | $2.37-2.41$ | $0.22-0.26$ | $0.17-0.19$ | $0.26-0.27$ | 3.16 c |
| $\mathbf{c}$ | Secondary | $2.20-2.68$ | $0.22-0.27$ | $0.15-0.28$ | $0.19-0.29$ | 3.16 c |

## Table 3.3 Summary of electron microprobe results for $\boldsymbol{N}$. anomala

The results displayed in Table 3.3 summarise the concentration range (i.e. the lowest concentration to the highest concentration) of $\mathrm{Mg}, \mathrm{Sr}, \mathrm{Na}$ and $S$ in the primary and secondary layers of N. anomala

In contrast to T. retusa, N. anomala has a high magnesium calcite shell. Magnesium concentrations attain a maximum of $2.76,3.73$ and $2.68 \mathrm{wt} \%$ respectively in the three specimens of $N$. anomala presented in Figure 3.16 (a-c). Magnesium concentrations vary little across the shells and there is no detectable difference in concentration between the primary and secondary layers. Sulphur, strontium and sodium concentrations are also invariant across the primary and secondary layers of the shell.

In common with data obtained for T. retusa, the mean values for the concentration of each element in the primary and secondary layers were analysed using ANOVA in order to determine if there are any significant differences in concentration between the two layers. Results indicate that there is no significant difference in element concentration between the primary and secondary layers of the shell (Table 3.4).

| Element | P-value |
| :---: | :---: |
| Sulphur | 0.785 |
| Magnesium | 0.466 |
| Calcium | 0.948 |
| Strontium | 0.137 |
| Sodium | 0.539 |

## Table 3.4 Results of Analysis of Variance for element concentration in the primary and secondary layers of Novocrania anomala

Figure 3.17 (a-e) presents boxplots of element concentration as a function of the shell layer. Each box represents the interquartile range of each data set, the mean values are represented as red circles. For the elements discussed here the spread of data for the primary and secondary layers lie within the same range and therefore the concentration of elements in each layer is not significantly different.

Chapter 3 Ultrastructure and Minor and Trace Element Composition

Figure 3.16 (a,b\&c) Electron microprobe spot analyses across the shell of Novocrania anomala

Electron microprobe analyses were carried out as described in Section 2.6.2. Elements displayed are above the limit of detection. Punctae (p)

Figure 3.17 (a-c) Boxplots of element concentration in the primary and secondary layers of Nowocrania anomala The mean values for the primary and secondary layer for nine sets of electron microprobe analyses of three specimens of N . anomala were analysed using ANOVA to determine if there is a significant difference in element concentration between the primary and secondary layers of the shell. Each bax represents the interquartile range (IQR) of the sample sel (i.e. QI-
Q3). Top and bontom whiskers extend from the bax to the highest and lowest values within Q1-1.5*IQR. Values outlying the range of the whiskers are marked as stars (*). Mean values are displayed as red circles.

Figure 3.18 displays scatter plots for data comprising three sets of analyses taken across the primary and secondary layers of three individuals of $N$. anomala. Correlation coefficients are presented in Table 3.5. There is some indication of a positive correlation between calcium and magnesium and between calcium and strontium in the secondary layer. There is a negative correlation between calcium and sodium in the primary and secondary layers and between strontium and sodium in the primary layer.

| N. anomala | Primary Layer |  | Secondary Layer |  |
| :---: | :---: | :---: | :---: | :---: |
| Variables | Correlation <br> Coefficient | P-value | Correlation <br> Coefficient | P-value |

| $\mathbf{S} / \mathbf{N a}$ | -0.375 | 0.054 | -0.052 | 0.477 |
| $\mathbf{M g / S r}$ | 0.002 | 0.994 | 0.303 | 0.000 |
| $\mathbf{M g / S}$ | -0.141 | 0.483 | -0.158 | 0.029 |
| $\mathbf{M g} / \mathbf{N a}$ | 0.322 | 0.102 | -0.333 | 0.000 |
| $\mathbf{C a} / \mathbf{N a}$ | -0.495 | 0.009 | -0.363 | 0.000 |
| $\mathbf{C a} / \mathbf{M g}$ | 0.100 | 0.619 | 0.464 | 0.000 |
| $\mathbf{C a} / \mathbf{S}$ | -0.095 | 0.636 | -0.240 | 0.001 |
| $\mathbf{C a} / \mathbf{S r}$ | 0.487 | 0.010 | 0.436 | 0.000 |
| $\mathbf{S r} / \mathbf{N a}$ | -0.491 | 0.009 | -0.180 | 0.014 |

Table 3.5 Pearson correlation coefficients with P-values for element concentration in the primary and secondary layers of $N$. anomala

Pearson correlation coefficients were calculated to determine the linear relationships between element concentrations in the primary and secondary layers of $N$. anomala. Values close to 1 indicate a strong positive linear correlation.

Figure 3.19 presents EDS maps of element concentration across a specimen of $N$. anomala. The maps concur with the data obtained from electron microprobe spot analyses (Figure 3.16) in that there is no detectable difference in element concentration between the primary and secondary layers of the shell and little variation across the whole specimen.

Figure 3.18 (a-j) Scatter plots of element concentration in the primary and secondary layers of Novocrania anomala
The concentration of minor elements in the primary and secondary layers of three specimens of N . anomala was analysed by electron microprobe as described in Section 2.6.2. The data from three sets of electron microprobe analyses from each specimen are plotted in order to determine any relationships between elements present within the shell.

Figure 3.19 X-ray maps of element concentration in Novocrania anomala
a. Mgk , b. Sk $\alpha$, c.Nak , d. Cak $\alpha$. A specimen of N. anomala was prepared for analysis as described in Section 2.6.1. Mapping was carried out as described in Section 2.6.4. For each map, light grey areas indicate a greater element concentration while dark grey areas indicate lower element concentration.

### 3.3.2.3 Cathodoluminescence Imaging and Spectroscopy

In optical CL $N$. anomala has an orange-red emission (Figure 3.20), in contrast to $T$. retusa. These images also pick out the laminae that form the secondary layer.

A hyperspectral map of luminescence from a specimen of $N$. anomala differs from the optical CL image (Figure 3.21a). The most intense emission is at blue wavelengths but the innermost area of the secondary layer has a peak at between $600-650 \mathrm{~nm}$ (Figure 3.21b), which produces the pink emission mixed with the blue (Figure 3.21a)

Figure 3.20 Cathodoluminescence image of Novocrania anomala
A thin section of a specimen of N . anomala was prepared as described in Section 2.5. The image was captured as described in Section 2.6.5.

Chapter 3 Ultrastructure and Minor and Trace Element Composition

(b)

Figure 3.21 (a) Hyperspectral image showing the intensity and wavelength of CL emission from a specimen of Novocrania anomala (b) CL emission spectrum acquired from Novocrania anomala

Cathodoluminescence spectroscopy was carried out as described in Section 2.6.6. The image was produced using the software, CHIMP. The red cross on the CL map corresponds to the red line spectrum while the green cross corresponds to the green line spectrum. Units on the Y axis of Figure 3.21(b) are arbitrary.

### 3.3.3 Mytilus edulis Ultrastructure and Minor Elements

### 3.3.3.1 Ultrastructure

The shell of Mytilus edulis has three layers; an outer organic periostracum and two inner mineralised layers (Figure 3.22). In contrast to the calcite shells of T. retusa and $N$. anomala. the mineralised layers of M. edulis are composed of calcite and aragonite. The organic periostracum is composed mainly of sclerotised proteins and acts as a substrate for initial crystal nucleation (Watabe, 1988). The calcite layer comprises prisms that are oriented in the same direction and each is encased in organic matrix (Figure 3.23). Underlying the calcite are layers of tabular aragonite crystals (Figure 3.24 and 3.25). Each crystal is offset from the underlying crystal to form a "brick wall" structure. All the crystals are aligned with the c axis almost perpendicular to the inner surface while the orientation of the $a$ and $b$ axes vary (Watabe, 1988).

Thin section photographs are presented in Figures 3.26 and 3.27. The calcite and aragonite layers and the boundary between the layers can be seen in both plane-polarised light and cross-polarised light images.

### 3.3.3.2 Minor Element Composition- Electron Microprobe Analysis

Electron microprobe spot analyses taken across the calcite and aragonite layers of specimens $a$ and $b$ of $M$. edulis are presented in Figure $3.28 a$ and $b$ respectively. Spot analyses were taken in a line perpendicular to the line of section. Magnesium, strontium, sodium and sulphur are all present in concentrations above detection limits. (Manganese, iron, potassium and phosphorus are below detection limits and therefore not discussed). Results are summarised in Table 3.6.

| Specimen | Polymorph | Mg Conc. <br> Range <br> $(\mathbf{w t \%})$ | Sr Conc. <br> Range <br> $\mathbf{( w t \% )}$ | Na Conc. <br> Range <br> $\mathbf{( w t \% )}$ | S Conc. <br> Range <br> $\mathbf{( w t \% )}$ | Figure <br> No. |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| a | Calcite | $0.05-0.18$ | $0.06-0.13$ | $0.05-0.22$ | $0.01-0.11$ | 3.28 a |
| a | Aragonite | $0-0.04$ | $0.07-0.32$ | $0.19-0.24$ | $0.01-0.06$ | 3.28 a |
| b | Calcite | $0.06-0.16$ | $0.04-0.14$ | $0.19-0.30$ | $0.03-0.11$ | 3.28 b |
| b | Aragonite | $0-0.01$ | $0-0.15$ | $0.12-0.30$ | $0.02-0.10$ | 3.28 b |

Table 3.6 Summary of electron microprobe results for M. edulis

The results displayed in Table 3.6 summarise the concentration range (i.e. the lowest concentration to the highest concentration) of $M g, S r, N a$ and $S$ in the calcite and aragonite layers of M . edulis

There is a difference in chemical composition between the calcite and aragonite in $M$. edulis. Magnesium concentrations are highest in the outer calcite layer ( 0.05 to $0.18 \mathrm{wt} \%$ and 0.06 to $0.16 \mathrm{wt} \%$ in specimens a and b respectively (Figure 3.28). The distribution of magnesium within the calcite layer varies between individuals, as is demonstrated by specimens $a$ and $b$ (Figure 3.28).

The maximum concentrations of sodium are comparable between the calcite and aragonite layers. Sodium reaches a maximum of $0.22 \mathrm{wt} \%$ and $0.24 \mathrm{wt} \%$ respectively in the calcite and aragonite layer of specimen a (Figure 3.28a), and $0.30 \mathrm{wt} \%$ in the calcite and aragonite layers of specimen $b$ (Figure 3.28b). In both specimens sodium concentration decreases across the calcite layer from the periostracum towards the polymorph boundary, while sodium concentration is relatively constant throughout the aragonite layer of the shell.

Analyses of specimen a indicate that strontium concentration is slightly greater in the aragonite layer than the calcite layer (Figure 3.28a) but this trend is not apparent in specimen b (Figure 3.29b) where the concentration of strontium is constant across the shell section. There is no evidence for a significant difference in sulphur concentration between the calcite and aragonite.

Figure 3.29 presents scatter plots of element concentration in M. edulis from six sets of spot analyses taken across both specimens of M. edulis. Correlation coefficients are presented in Table 3.7. Within the calcite layer there is a strong positive correlation between sulphur, strontium and sodium (Table 3.7). Magnesium and sodium display a negative correlation in the aragonite layer. There is a positive correlation between strontium and sodium in the calcite layer while there is a negative correlation in the aragonite layer (Figure 3.29j and Table 3.7).

|  | Calcite Layer |  | Aragonite Layer |  |
| :---: | :---: | :---: | :---: | :---: |
| M. edulis | Correlation <br> Coefficient |  | P-value | Correlation <br> Coefficient |
| $\mathbf{S / S r}$ | 0.608 | 0.000 | 0.204 | P-value |
| $\mathbf{S} / \mathbf{N a}$ | 0.826 | 0.000 | -0.220 | 0.219 |
| $\mathbf{M g / S r}$ | 0.091 | 0.347 | 0.089 | 0.185 |
| $\mathbf{M g / S}$ | 0.028 | 0.774 | 0.130 | 0.596 |
| $\mathbf{M g} / \mathbf{N a}$ | 0.136 | 0.157 | -0.787 | 0.437 |
| $\mathbf{C a} / \mathbf{N a}$ | -0.015 | 0.873 | 0.300 | 0.000 |

| $\mathbf{C a} / \mathbf{S}$ | 0.041 | 0.675 | -0.068 | 0.687 |
| $\mathbf{C a} / \mathbf{S r}$ | 0.086 | 0.375 | -0.304 | 0.063 |
| $\mathbf{S r} / \mathbf{N a}$ | 0.658 | 0.000 | -0.391 | 0.015 |

Table 3.7 Pearson correlation coefficients with P-values for element concentration in the calcite and aragonite layers of M. edulis

Pearson correlation coefficients were calculated to determine the linear relationships between element concentrations in the calcite and aragonite layers of M. edulis. Values close to 1 indicate a strong positive linear correlation.

Figure 3.30 displays maps of the distribution of magnesium, sulphur, sodium and calcium in a specimen of $M$. edulis. Magnesium concentration is greater in the calcite layer of the shell (Figure 3.30a). The element maps do not highlight any variation in sulphur, sodium and calcium concentration between the calcite and aragonite layers of the specimen possibly as the X-ray mapping is insensitive to the slight differences in concentration of some elements between the calcite and aragonite.

Chapter 3 Ultrastructure and Minor and Trace Element Composition

Figure $3.28(\mathrm{a} \mathrm{\& b})$ Electron microprobe spot analyses of Mytilus edulis

Electron microprobe analyses were carried as described in Section 2.6.2. Elements displayed are above the limit of detection.

## Figure 3.29 Scatterplots of element concentration in Mytilus edulis

The concentration of minor elements in the calcite and aragonite layers of two specimens of M.edulis was analysed by electron microprobe as described in Section 2.6.2. The data from three sets of analyses from each specimen are plotted in order to determine if any relationships exist between elements present within the shell.

Figure 3.30 X-ray maps of element distribution in a specimen of Mytilus edulis
a. Mgka, b. Ska, c. Nakc, d. Caka. A specimen of M. edulis was prepared for analysis as described in Section 2.6.1 and mapping was carried out as described in Section 2.6.4. For each map light grey areas indicate a greater element concentration while dark grey areas indicate lower element concentration. The boundary between the calcite and aragonite layers is marked by a red dashed line.

### 3.3.3.3 Cathodoluminescence Imaging and Spectroscopy

The optical CL image of M. edulis (Figure 3.31) shows a faint luminescence from the outer calcite layer but most of the layer is non-luminescent. The aragonite layer displays faint white/blue luminescence.

Figure 3.31 Cathodoluminescence image of a specimen of Mytilus edulis

A specimen of M . edulis was embedded in a resin block and prepared as described in Section 2.6.1. The image was captured as described in Section 2.6.5. The boundary between the calcite and aragonite layers is marked by a red dashed line.

In the hyperspectral map of M. edulis (Figure 3.32a) the calcite and aragonite layers have comparable peak wavelengths of emission but the intensity of luminescence differs both between the layers and within the aragonite layer (Figure 3.32b). A large proportion of the luminescence emitted from the specimen lies within the blue range of the visible spectrum (around 410 nm ) (Figure 3.32b). In this case dark blue areas of the CL map (Figure 3.32a) do not result from beam damage to the sample.

Figure 3.32 (a) Hyperspectral image showing the intensity and wavelength of CL emission from a specimen of Mytilus edulis, (b) CL emission spectrum acquired from Mytilus edulis

Cathodoluminescence spectroscopy was carried as described in Section 2.6.5. The image was produced using the software, CHIMP. The colour of the cross on the CL map corresponds to the same colour of line spectra. The division between the calcite and aragonite layers is marked by a red line. Units on the y axis of Figure $3.32 b$ are arbitrary.

### 3.3.4 Avian eggshell (Gallus gallus) Ultrastructure and Minor Elements

### 3.3.4.1 Ultrastructure

The eggshell of the domestic fowl (Gallus gallus) consists of six regions; the inner and outer shell membranes which provide a surface for crystal nucleation, the mammillary caps. the palisade layer, the vertical crystal layer and an outer organic cuticle (Figure 3.33 and Figure 3.34).

Removal of the membrane (Section 2.2) reveals the mammillary caps (Figure 3.35), which are the first part of the shell to form. The most common mammillary cap structure found in the eggshell is presented in Figure 3.36 where the mammillary bodies are in close contact with each other and also the membrane, which leaves an imprint on the base of the mammillary caps (Solomon, 1991). Solomon (1991) described these mammillary caps and also identified the presence of two other types of mammillary body, termed Type A and Type B. Type A consists of conical shaped bodies that have minimal contact with the membrane while Type $B$ consist of rounded structures that are in contact with the membrane (Figure 3.36).

As the mammillary caps grow they fuse and continued growth produces the palisade layer and the vertical crystal layer, which consists of columnar crystals aligned perpendicularly to the palisade layer. The organic cuticle, which covers the vertical crystal layer consists of an inner vesicle layer with vesicles which contain phosphorus and an outer non vesicular layer (Fraser, 1996, Dennis et al. 1996).

Figure 3.33 Secondary electron image of a section through an avian eggshell (Gallus gallus)

SEM image of a fractured section of a specimen of an eggshell. The section displays the membrane fibres (MF), the mammillary caps (MC), the palisade layer $(P)$ and the cuticle(C).

### 3.3.4.2 Minor Element Composition-Electron Microprobe Analysis

Electron microprobe analyses were taken across the eggshell in a line perpendicular to the line of section (Figure 3.37). Magnesium, strontium, sodium, phosphorus and potassium are all above the limit of detection of the SX 50 electron microprobe. Sulphur is below the limit of detection and therefore will not be discussed. Results are summarised in Table 3.8.

| Specimen | Mg Conc. <br> Range <br> $\mathbf{( w t \% )}$ | Sr Conc. <br> Range <br> $(\mathbf{w t \%})$ | Na Conc. <br> Range <br> $(\mathbf{w t \%} \%$ | P Conc. <br> Range <br> $(\mathbf{w t \%} \%$ | K Conc. <br> Range <br> $(\mathbf{w t \%} \%$ | Figure <br> No. |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| a | $0.13-0.64$ | $0-0.06$ | $0.02-0.12$ | $0.01-0.10$ | $0.01-0.03$ | 3.37 a |
| b | $0.09-0.59$ | $0-0.03$ | $\mathrm{n} / \mathrm{a}$ | $0-0.12$ | $0-0.03$ | 3.37 b |

## Table 3.8 Summary of electron microprobe results for G. gallus eggshell

The results displayed in Table 3.8 summarise the concentration range (i.e. the lowest concentration to the highest concentration) of $\mathrm{Mg}, \mathrm{Sr}, \mathrm{Na}, \mathrm{P}$ and K in the eggshell of G . gallus

Figure 3.37 a and b illustrate spot analyses of magnesium, sodium, phosphorus and potassium taken across two eggshell specimens. There is a high concentration of magnesium within the mammillary caps in both specimens. Magnesium concentrations abruptly decrease across the zone in which the mammillary caps fuse and then steadily increase through the shell towards the cuticle. Phosphorus and potassium concentrations gradually increase from the mammillary caps to the outer cuticle. Both phosphorus and potassium reach maximum concentration during termination of shell growth. Strontium displays a similar but more erratic pattern, gradually increasing towards the outer portion of the shell. Sodium concentration is at a maximum in the mammillary caps and gradually declines across the area in which the mammillary caps fuse. Unfortunately sodium analyses are not available for specimen $b$.

Scatter plots of element concentration are presented in Figure 3.38. Correlation coefficients are presented in Table 3.9. The graphs include four sets of spot analyses taken across two specimens of eggshell. From spot analysis (Figure 3.37) the distributions of some elements follow a similar trend. Magnesium positively correlates with phosphorus
(Figure 3.38a and Table 3.9). Within this plot there is a separate cluster of four data points that were obtained from the eggshell cuticle. Magnesium also displays a positive correlation with potassium (Figure 3.38i), while phosphorus and potassium also show a strong positive correlation (Figure 3.38e). Calcium displays a negative correlation with magnesium (Figures3.38f and Table 3.9). Sodium displays a negative correlation with potassium (Table 3.9).

| Variables | Correlation Coefficient | P-value |
| :---: | :---: | :---: |
| $\mathrm{Mg} / \mathrm{P}$ | 0.711 | 0.000 |
| $\mathrm{Sr} / \mathrm{P}$ | 0.462 | 0.000 |

Table 3.9. Pearson correlation coefficients with P-values for element concentration in the calcite eggshell of G. gallus

Pearson correlation coefficients were calculated to determine the linear relationships between element concentrations in the calcite shell of G . gallus. Values close to I indicate a strong positive linear correlation.

X-ray maps showing the distributions of a number of elements are illustrated in Figure 3.39. As shown by electron microprobe data, the highest concentration of magnesium is within the mammillary caps and the cuticle (Figure 3.39a). Although sulphur concentrations are below detection limits the sulphur X-ray map (Figure 3.39b) highlights
the sulphur rich organic membrane upon which the shell nucleates. Figure 3.39 d displays the high concentration of phosphorus in the cuticle.

Figure 3.37 (a \& b) Electron microprobe spot analyses across the avian eggshell

Specimens were prepared for electron microprobe analysis as described in Section 2.6.1. Electron microprobe analyses were carried out as described in Section 2.6.2.

Figure 3.38 ( $a-0$ ) Scatterplots of element concentration in the avian eggshell (Gallus gallus)
The concentration of minor elements in two specimens of Gallus gallus eggshell were analysed by electron microprobe as described in Section 2.6.2. The data from rwo sets of analyses from each specimen are plotred in order to determine if any relationships exist berveen elements present within the shell. Data points hecome more scaltered as element concentrations approach the limit of detection.

Figure 3.39 X-ray maps of element concentration in an avian eggshell (Gallus gallus)
a. Mgka, b. Sk $\alpha$, c. Cakc, d. Pk $\alpha$. A sample of an eggshell was prepared for analysis as described in Section 2.6 .1 and mapping was carried out as described in Section 2.6.4. For each map, light grey areas indicate a greater element concentration while dark grey areas indicate lower element concentration.

### 3.3.4.3 Cathodoluminescence Imaging and Spectroscopy

The avian eggshell of Gallus gallus luminesces white in optical CL (Figure 3.40), but predominantly at blue wavelengths in the hyperspectral maps (Figure 3.41a), although there is also some emission within the ultraviolet range of the spectrum (less than 400 nm ) (Figure 3.41b).

Figure 3.40 Optical CL image of a specimen of the avian eggshell (Gallus gallus)

A specimen of an avian eggshell (Gallus gallus) was prepared as described in Section 2.6.1. The image was captured as described in Section 2.6.5.

b
Figure 3.41 (a) Map of cathodoluimnescence emission from a specimen of an eggshell (Gallus gallus), (b) Spectrum of luminescence emission from an eggshell (Gallus gallus)

Cathodoluminescence spectroscopy was carried as described in Section 2.6.6. The image was produced using the software, CHIMP. The red cross on the CL map corresponds to the red line spectra in Figure 3.41b. Units on the $Y$ axis of Figure 3.41 b are arbitrary.

### 3.4 Discussion

### 3.4.1 Terebratulina retusa and Novocrania anomala

As T. retusa and $N$. anomala were collected from the same location, they have experienced identical environmental conditions throughout ontogeny. The shell chemistry of each species can therefore be compared without having to consider possible effects of environmental variables. The shell of $T$. retusa is composed of low magnesium calcite, while the shell of $N$. anomala is high magnesium calcite, demonstrating that the main influences on the skeletal chemistry of these two species are biological rather than environmental.

The distribution of minor elements through the low magnesium calcite shell of $T$. retusa is distinctive. There is a significant difference in magnesium, calcium, sulphur, and strontium concentrations between the primary and secondary layers, with a higher concentration of magnesium, sulphur and strontium in the primary layer of the shell. The shell of $N$. anomala has a high organic matrix content (Section 4.3.1) and a greater concentration of minor elements than that of $T$. retusa, while electron microprobe analyses show that the distribution of elements across the primary and secondary layers is relatively invariant.

There have been a number of suggestions of the principal controls on the distribution of magnesium and other trace elements in calcium carbonate skeletons, including growth rate (Buening and Carlson, 1992) and temperature (Lowenstam, 1961, Dodd, 1967 and Lowenstam and Weiner, 1989). A number of studies have indicated that a high magnesium concentration in abiotic calcite is associated with rapid precipitation rates (Major and Wilber, 1991 and Burton and Walter, 1987). Auclair et al., (2003) showed that the secondary layer of Terebratalia transversa is divided into two layers in terms of ultrastructure and isotopic composition. The variation in $\delta^{18} \mathrm{O}$ between the two sections of the secondary layer is related to kinetic fractionation, as the growth rates of the primary and upper secondary layers, secreted by the marginal mantle are faster than that of the lower section of the secondary layer which is secreted by the posterior mantle (Auclair et al., 2003 and Rosenberg et al., 1988).

Curry (1982) found that the brachiopod T. retusa grows rapidly during the first three years of life and especially during the first three months, at the end of which it attains an average length of 2.75 mm . The growth rate declines with age (Curry, 1982). Buening and Carlson (1992) found evidence that the trace element composition of the articulated brachiopods $T$. unguicula and $T$. transversa is influenced by changes in growth rate throughout ontogeny, where higher magnesium concentrations within the shell correlate to periods of faster growth. Variations in growth rate during ontogeny may therefore similarly influence the minor element composition of $T$. retusa.

A division between upper and lower sections of the secondary layer of T. retusa is evident both in thin section (Figures 3.4 and 3.5 ) and in chemical differences between the two sections (Figure 3.6b). If the primary and upper secondary layers are precipitated more rapidly than the lower secondary layer, as is the case for $T$. transversa (Auclair et al. 2003), then one would expect that the concentration of magnesium would be greater in the primary and upper secondary layers in comparison to the lower secondary layer.

If growth rate does exert a control over magnesium incorporation in calcite then it would be expected that this factor would influence the trace element composition of carbonate shells of other species. Novocrania anomala however, is a slow growing brachiopod with a high magnesium calcite shell (Ruggiero, 2001). This suggests that growth rate is not the sole factor which influences shell chemistry.

Rosenberg and Hughes (1991) propose that growth rate and composition of the shell of the bivalve M. edulis are a function of the metabolic activity of the mantle. They suggest that mantle metabolism is highest where the shell is chemically expensive to produce and that the growth rate of the shell varies according to both the relative metabolic rate of the mantle and the concentration of organic matrix and trace elements within the newly formed shell. In specimens of M. edulis, they determined that calcium rich, fast growing areas of the shell were underlain by mantle with a low metabolic activity while areas of the shell that are rich in organic matrix and trace element content and are slow growing and are underlain by mantle with a high metabolic activity. Rosenberg et al., (1988) found evidence for a decline in both metabolic activity and growth rate with age in the brachiopod T. transversa. Rosenberg et al., (1988) found that the metabolic activity of the marginal mantle, which forms the primary and upper secondary layer of $T$. transversa is higher than that of the posterior mantle, which forms the lower secondary layer. If the
metabolic activity of the mantle of $T$. retusa is similar to that of $T$. transversa then the marginal mantle, which produces the magnesium and sulphur-rich primary and upper secondary layers, may have a higher metabolic rate than the posterior mantle which produces the lower secondary layer. The decrease in trace element and matrix content may therefore be related to a decrease in metabolic activity throughout ontogeny. It should be recognised however that there are significant differences in the metabolism of bivalves and brachiopods and the extrapolation of theories from one system to another can be problematic.
N. anomala is a slow growing brachiopod with a high magnesium, organic rich calcite shell. If the trace element concentration and distribution through the shell of $N$. anomala reflects the metabolic activity of the mantle then the data presented in Section 3.3.2.2 suggests that the metabolic rate of the mantle is relatively stable throughout ontogeny as there is no significant difference in minor element concentration between the primary and secondary layers of the shell.

The data available on the metabolism of inarticulated brachiopods is limited and no information is available about the metabolism of $N$. anomala. Therefore the relationship between matrix/mineral ratios and metabolic rate can only be surmised. Hammen (1971) found that the inarticulated brachiopod Lingula, has a higher metabolic rate than the articulated brachiopods. This data concurs with the metabolic rate theory suggested by Palmer (1981) and Rosenberg et al., (1991) as Lingula has an organic rich shell which would be metabolically expensive to produce.

Stanley et al., (2002) found that simple organisms such as algae are passive in the uptake of magnesium from seawater and therefore have high magnesium calcite skeletons due to the high magnesium content of present day oceans. The high magnesium content of the calcite shell of $N$. anomala suggests that $N$. anomala does not have a physiological mechanism to exclude magnesium unlike those species which produce low magnesium calcite shells (Lowenstam and Weiner, 1989, Lorens and Bender, 1977 and Nurnberg et al., 1996).

Sulphur is thought to be a reliable indicator of the distribution of organic matrix within calcium carbonate biominerals (Dauphin et al., 2003a and 2003b). In the molluscs Pinna and Pinctada, sulphur is associated with the intercrystalline and intracrystalline organic matrix as sulphated mucopolysaccharides and the amino acids, methionine and cysteine
(Dauphin et al. 2003a). The correlation between magnesium and sulphur within the shell of T. retusa (Section 3.3.1.2) indicates that, in this case, magnesium may be associated with the organic matrix.

Maps of element concentration across the shell of T. retusa also highlight the relationship between magnesium and sulphur. The areas of high magnesium and sulphur content, which extend from the primary layer into the secondary layer are assumed to be extensions of the primary layer organic matrix crossing the boundary between the two layers. It is unlikely that these areas of high sulphur and magnesium concentration are associated with the mineral as no evidence has been found for extensions of the primary layer ultrastucture into the secondary layer. The high concentration of sulphur in the primary layer of $T$. retusa may be further due to a higher concentration of organic matrix in the primary layer in comparison to the secondary layer or a difference in the composition of the organic matrix between the two layers. If magnesium is associated with the organic matrix then this has implications for the biomineralisation mechanisms involved in the formation of the shell of $T$. retusa. The application of $\mathrm{Mg} / \mathrm{Ca}$ ratios as palaeotemperature indicators in both the Brachiopoda and other taxa may also need to be considered since it is based on the assumption that Mg substitutes for Ca in the carbonate structure. These results suggest that, in some cases Mg is associated with the organic matrix and is not a true component of the carbonate structure.

Sulphate can also be accommodated within the calcite lattice as well as the organic matrix, while the negative relationship between calcium and minor elements such as magnesium can also be accounted for by the substitution of ions for $\mathrm{Ca}^{2+}$ in the lattice. As electron microprobe analysis does not distinguish between sources of ions it cannot be confirmed conclusively which phase the sulphur and other elements are associated with.

In $N$. anomala, sulphur does not correlate with the other elements indicating that the minor elements are concentrated in the crystal lattice rather than the organic matrix. The difference in peak position between XRD analyses of the low magnesium calcite shell of $T$. retusa and the high magnesium calcite shell of $N$. anomala indicate that the magnesium ions are encompassed within the calcite lattice of the $N$. anomala shell. It is also likely that strontium and sodium ions are also present within the lattice as they do not correlate with sulphur.

The concentration of minor elements in the shells of brachiopods may also be related to environmental conditions (Lee et al., 2004 and Buening and Carlson, 1992). The data presented here indicates that the main trends may be related to physiological parameters. As environmental data are not available for this study, the influence of variations in environmental conditions on shell composition cannot be determined.

### 3.4.2 Mytilus edulis

The main factor determining chemical variations within the shell of M. edulis is the crystal structure of $\mathrm{CaCO}_{3} . \mathrm{Mg}^{2+}$ readily substitutes for $\mathrm{Ca}^{2+}$ in the calcite lattice, but not as easily within the aragonite lattice. The strontium ion however, is larger than $\mathrm{Mg}^{2+}$ and readily fits into the more open orthorombic structure of the aragonite lattice. Differences in the concentrations of magnesium and strontium between the two layers can therefore to some extent be explained by contrasts in their crystal structure.

Sodium is present in relatively high concentration in both the calcite and aragonite layers. Electron microprobe data show that the concentration of sodium decreases across the calcite layer towards the boundary with aragonite. It is difficult however, to determine whether the sodium is present in the calcite-crystal lattice or associated with the organic matrix. Unlike $\mathrm{Mg}^{2+}$ and $\mathrm{Sr}^{2+}$ that can substitute for $\mathrm{Ca}^{2+}$, sodium is monovalent and cannot so easily substitute for $\mathrm{Ca}^{2+}$. Ions such as $\mathrm{Na}^{+}$may however sit in interstitial spaces and particularly within crystal lattice defects (Busenberg and Plummer, 1985).

Sulphur concentrations are low and are similar across the calcite and aragonite layers. As in the two brachiopods, sulphur may also be present in the calcite lattice as $\mathrm{SO}_{4}$. If $\mathrm{Sr}^{2+}$ is also present within the calcite crystal lattice then the number of crystal defects is likely to increase due to the larger ionic radius of strontium in comparison to the $\mathrm{Ca}^{2+}$ ion for which it substitutes. This may result in the incorporation of more $\mathrm{Na}^{+}$into the crystal defects, which may also account for the strong positive correlation between strontium and sodium. However following the work by Dauphin et al. (2003a), which determined that sulphur is associated with glycosaminoglycans within the organic matrix of molluscs, sulphur is likely to be associated with the organic matrix. It has also been confirmed that sulphated sugars are contained within the organic matrix of M. edulis (See Section 4.3.4). Both strontium and sodium positively correlate with sulphur in the calcite layer of the shell, therefore strontium and sodium may be associated with the organic matrix in the calcite
layer. The decrease in sodium from the outer periostracum through the calcite layer to the polymorph boundary suggests that there may be either a change in the structure of the calcite thus affecting sodium incorporation, or a decrease in the concentration of organic matrix.

There is some evidence for a correlation between strontium and sodium in the aragonite layer of the specimens in Section 3.3.3.2. There is also a variation in the concentration of sodium, sulphur, strontium and magnesium across the aragonite layer. Lorens and Bender (1980) found that both the $\mathrm{Sr} / \mathrm{Ca}$ and $\mathrm{Mg} / \mathrm{Ca}$ values of $M$. edulis aragonite increased linearly with increasing $\mathrm{Sr} / \mathrm{Ca}$ and $\mathrm{Mg} / \mathrm{Ca}$ in solution. While the $\mathrm{Sr} / \mathrm{Ca}$ value of the calcite layer also increased linearly with increasing $\mathrm{Sr} / \mathrm{Ca}$ in solution the $\mathrm{Mg} / \mathrm{Ca}$ ratio of the calcite increased exponentially with $\mathrm{Mg} / \mathrm{Ca}$ in solution (Lorens and Bender, 1980). As with the carbonate skeletons of other marine organisms however, the magnesium content of $M$. edulis is lower than that predicted from inorganic distribution coefficients, possibly because M. edulis has a physiological mechanism for exclusion of magnesium (Lorens and Bender, 1977).

As discussed in Section 3.4.1, Rosenberg and Hughes (1991) described an inverse relationship in the calcite layer of $M$. edulis between matrix/trace element rich shell and metabolic activity. From the analyses described in Section 3.3.3.2 this relationship cannot be confirmed, although a number of other authors have also found evidence to suggest that the metabolic activity of the mantle in certain bivalves influences the trace element composition and the concentration of organic matrix within the shell (Klein et. al, 1996).

### 3.4.3 Eggshell

The ionic composition of the uterine fluid may control the minor element composition of the eggshell. Electron microprobe analyses of the G. gallus eggshell (Figure 3.37) indicate that the concentration of magnesium is high in the mammillary caps and abruptly decreases towards the area of the shell within which the mammillary caps fuse. Furthermore, magnesium concentration gradually increases from the point at which the mammillary caps fuse towards the cuticle. The concentration of magnesium in the uterine fluid increases throughout the three phases of eggshell formation: initial $(0.8 \mathrm{mM})$, growth $(4 \mathrm{mM})$ and final phases ( 9 mM ) (Arad et al., 1989). In general, the magnesium concentration of the eggshell (Figure 3.37) follows the same pattern as variations in magnesium concentration
within the uterine fluid (i.e. magnesium concentration increases during the development of the eggshell). However, magnesium concentration within the mammillary caps is initially high. The discrepancy between the concentration of magnesium in the first formed part of the shell and the magnesium concentration within the uterine fluid may be a result of the time at which the first uterine fluid samples were extracted. Nys et al., (1991, 1999) also present measurements of the ionic composition of the uterine fluid during the initial and final stages of eggshell formation. Sodium concentration in the uterine fluid is high during initial precipitation and decreases throughout the calcification process. This pattern is consistent with the distribution of sodium in the eggshell, which increases from the earliest formed part of the shell i.e. the mammillary caps to the outer shell cuticle (Figure 3.37). Potassium concentration in the uterine fluid increases during the final stages of shell formation, which corresponds with an increase in potassium through the palisade layer to the outer cuticle (Figure 3.37). Phosphorus concentration in the uterine fluid is also at its highest during the later stages of eggshell calcification, which is also consistent with the distribution of phosphorus in the eggshell (Figure 3.37).

Hincke and St. Maurice (1998) found that the addition of $\mathrm{Mg}^{2+}$ to calcite crystal growth solution accelerated the onset of calcite precipitation but inhibited the maximum rate of precipitation with respect to a control experiment. The addition of phosphate ions also resulted in the inhibition of the maximum precipitation rate. The influence of magnesium on calcite crystal morphology has also been reported (Meldrum and Hyde, 2001). Ions such as magnesium and phosphate may therefore have an active role in the formation of the eggshell and controlled changes in the ionic composition of the uterine fluid may therefore be a mechanism for controlling the onset of calcite precipitation, the precipitation rate and crystal morphology.

## 4 Organic Matrix Composition

### 4.1 Introduction

Biominerals are composite materials composed of a mineral phase with an organic matrix comprised of proteins, carbohydrates and lipids. The organic components control the nucleation, polymorph type and crystal morphology of the mineral (Lowenstam and Weiner, 1989, Simkiss and Wilbur, 1989). The matrix can be divided into two components: the intercrystalline organic matrix, which surrounds the crystals and the intracrystalline organic matrix which is present within the mineral itself and as such is resistant to strong chemical oxidation (Sykes et al., 1995). The matrix can also be divided into insoluble and soluble fractions by the demineralisation of the biomineral with ethylene diamine tetra acetic acid (EDTA). The insoluble fraction differs in composition between species and in some instances is absent (Weiner et al., 1983). These hydrophobic macromolecules provide a framework for crystal formation and as such are frequently referred to as "framework proteins". They exert control over crystal orientation and contribute to the final mechanical properties of the biomineral (Feng et al., 2000a), while it has also been suggested that they may influence the mineral polymorph type (Matsushiro et al., 2003). In contrast, the soluble matrix components are hydrophilic, contain a high proportion of acidic residues (Weiner et al., 1983) and are commonly glycosylated (Hare, 1963, Weiner and Hood, 1975, and Weiner, 1979). The acidic nature of these macromolecules has led to the suggestion that they have a calcium-binding function and as such an important role in the mineralisation process (Weiner and Hood, 1975, Weiner and Traub, 1984 and Lowenstam and Weiner, 1989). A number of in vitro studies have confirmed that organic matrix macromolecules extracted from different biomineral systems exert control over crystal growth and morphology (Belcher et al., 1996).

Organic matrices extracted from a range of biomineral systems have been characterised in relation to their protein composition and carbohydrate content (e.g. Cariolou and Morse, 1988, Hare, 1963, Panheleux et al. 2000, Kawaguchi and Watabe, 1993) and a number of comparative studies of matrix composition between species from the same phylum have been undertaken (e.g. Mitterer, 1978, Young, 1971 and Miyamoto, et al., 2003) yet relatively few comparisons of species from different phyla (e.g. Dauphin, 2001) have been carried out.

The aim of this chapter is to compare the organic matrix composition of the four systems, including different phyla which produce different ultrastructures and two types of calcium carbonate polymorph; calcite and aragonite. This chapter describes the molecular weight, charge and amino acid composition of intercrystalline and intracrystalline proteins as well as the carbohydrate organic matrix component of the shells of T. retusa, N. anomala, M. edulis and Gallus gallus.

### 4.2 Previous Work

### 4.2.1 Organic Matrix Structure and Control of the Mineral Phase

The general model for the structure of the organic matrix comprises a framework of hydrophobic macromolecules i.e. the insoluble organic matrix, with hydrophilic macromolecules i.e. the soluble organic matrix anchored at sites on the framework surface. Weiner and Traub (1984) and Weiner et al., (1983) proposed a model termed the template model, for the structure of organic matrix within the aragonite layer of molluse shells. This model comprises a core layer of insoluble chitin and silk fibroin like protein covered on both sides by layers of soluble matrix. Certain layers that form the matrix framework appear to be absent in some mollusc species while the acidic soluble matrix components are widespread, which suggests that the soluble matrix components have a different role to the insoluble matrix proteins in the mineralisation process (Weiner et al., 1983).

The template model requires that the arrangement of the aspartic acid residues in the soluble organic matrix match the crystallographic arrangement of $\mathrm{Ca}^{2+}$ in the lattice of aragonite (Weiner and Traub 1984). Weiner and Hood (1975) found a high concentration of glycine and aspartic acid in the soluble organic matrices of the molluscs, Crassostrea virginica, Mercenaria mercenaria, Crassostrea irredecens and Nautilus pompilus. The presence of proteins with a repeat (Asp- Y$)_{\mathrm{n}}$ sequence where the Y is glycine or serine was therefore inferred. If this repeat sequence is present in $\beta$-pleated sheet formation then there is a correlation between the carboxylate groups of the aspartic acid residues and the crystallographic arrangement of $\mathrm{Ca}^{2+}$ in the calcite and aragonite lattices (Weiner and Hood, 1975 and Weiner and Traub, 1984). However, this model does not explain the selective mineralisation of calcite and aragonite in the molluse shell, as the distances between calcium ions in the ( 001 ) face of calcite are similar to the distances between calcium ions in the (001) face of aragonite (Mann, 1988, 2001). The correlation between
crystal lattice stereochemistry i.e. the arrangement of $\mathrm{CO}_{3}{ }^{2-}$ anions around the $\mathrm{Ca}^{2+}$ ions as well as the location of the $\mathrm{Ca}^{2+}$ ions, and the molecular arrangement of the organic matrix may therefore exert control over the mineral phase and the polymorph that it nucleates (Mann, 2001).

### 4.2.2 Insoluble matrix composition

The dissolution of calcium carbonate biominerals with the calcium chelator Ethylene diamine tetra acetic acid (EDTA) results in two fractions of organic matrix, an EDTA insoluble fraction and an EDTA soluble fraction. The concentration of insoluble organic matrix varies significantly between species and in some instances the insoluble organic matrix is entirely absent which suggests that it has a different role in the mineralisation process than the soluble organic matrix (Weiner et al., 1983). The insoluble matrix proteins provide a framework upon which the soluble matrix fraction is anchored, and upon which mineralisation takes place. It has also been suggested that the main purpose of the insoluble matrix may be to influence the mechanical properties of the biomineral and may not have a major role in the mineralisation process itself (Lowenstam and Weiner, 1989, Feng et al., 2000a).

A high concentration of glycine within the organic matrix fraction is a common characteristic of the insoluble fraction of the organic matrix of calcium carbonate biominerals such as the shells of molluscs, brachiopods and bryozoans (Weiner et al., 1983). In mollusc shells, a group of fibrous framework proteins have been identified with a high concentration of both glycine and alanine (Miyashita et al., 2000, Kawaguchi and Watabe, 1993, Weiner et al., 1983 and Hare, 1963). Sudo et al., (1997) extracted two proteins, MSI 60 and MSI 31 from the shell of Pinctada fucata. Both proteins are thought to be framework proteins as they show no evidence of N -glycosylation or carbonic anhydrase activity both of which are features associated with the soluble acidic matrix proteins (Section 4.2.4). Lustrin A, a protein identified as a component of the shell matrix of the mollusc Haliotis refuescens has a combination of multifunctional structures which indicates that it serves a number of functions as well as being a structural framework protein (Shen et al., 1997). Lustrin A is homologous with other organic matrix proteins including the protein group, frustulins, which are associated with diatom cell walls (Shen et al., 1997). Data on the composition of the insoluble organic matrix of brachiopods is limited. Jope (1965) found that the exoskeletons of articulated brachiopods are enriched in glycine while the shell of the inarticulated brachiopod, Crania is also enriched in glycine
but to a lesser extent than the articulated brachiopods. Cusack et al., (2000) also found that the shells of the articulated brachiopod $T$. retusa and the inarticulated brachiopod $N$. anomala both had a high glycine content. In T. retusa the ventral valve is enriched in glycine but depleted in alanine with respect to the dorsal valve. It is suggested that the difference in amino acid composition is the result of the presence of the loop in the dorsal valve of the $T$. retusa shell (Cusack et al., 2000). In N. anomala the amino acid composition of the dorsal and ventral valves are quite different due to the differences in ultrastructure between the two valves.

### 4.2.3 Soluble matrix composition

Soluble matrix proteins extracted from both calcium carbonate biominerals and calcium phosphate biominerals such as bone and dentine, contain a high concentration of acidic amino acids (Lowenstam and Weiner, 1989. Mitterer, 1978. Mann, 2001 and Veis and Perry, 1967). These negatively charged macromolecules are thought to have a calcium binding function (Weiner, 1979, Wheeler et al., 1981 and Weiner and Hood, 1975). The effect of the soluble matrix on crystal growth and morphology is thought to differ depending on whether the macromolecules are fixed to a framework in which case they act as a nucleating surface for crystals, or if they are free in solution where they have been found to act as inhibitors of nucleation (Lowenstam and Weiner, 1989 and Wheeler et al., 1981). However, Weiss et al., (2000) have identified the soluble protein Perlucin from the shell of Haliotis laevigata, which when in solution enhances rather than inhibits calcite nucleation. Soluble matrix proteins extracted from the exoskeletons of bivalve molluscs not only influence the crystal morphology but also exert control over the polymorph type (Belcher et al., 1996 and Falini et al., 1996). The roles of the soluble and insoluble organic matrices in polymorph control are not fully understood however, and evidence has also been found for the precipitation of aragonite in vitro with the addition of a water insoluble protein complex extracted from the pearls and nacreous shell layers of specimens of the oyster, Pinctada fucata (Matsushiro et al., 2003). Control over polymorph type may therefore be the result of a complex interaction of both soluble and insoluble organic matrices and minor elements (e.g. magnesium) with the mineral precipitate (See Section 3.2.1).

Some proteins extracted from the shells of molluses have carbonic anhydrase activity. Miyamoto et al. (1996) isolated a soluble organic matrix protein, Nacrein from the nacreous layer of the pearl oyster Pinctada fucata and from the shell of the gastropod

Turbo marmoratus (Miyamoto et al., 2003), while Kono et al. (1999) cloned a soluble matrix protein, N66 from the shell of Pinctada fucata. All three proteins have carbonic anhydrase domains, which are thought to be involved in the calcification process. Miyamoto et al (1996) and Shimomura et al. (2002) suggest that the nacreins are involved in the calcification process during the conversion of respiratory $\mathrm{CO}_{2}$ to $\mathrm{HCO}_{3}{ }^{-}$in the presence of $\mathrm{H}_{2} \mathrm{O}$. Carbonic anhydrase activity increases the formation rate of calcium carbonate in vitro (Shimomura et al., 2002). The faster the rate of formation of $\mathrm{HCO}_{3}{ }^{-}$, the faster the rate of precipitation of calcium carbonate (Shimomura et al., 2002).

A large proportion of the soluble organic matrix proteins that have been extracted from the shells of marine invertebrates and from eggshells are glycosylated (Cusack et al., 2000, Collins et al., 1991 \& Ameye et al., 2001). Cusack et al., (2000) identified two glycoproteins of 40 KDa and 62 KDa molecular weight in the soluble organic matrix of $T$. retusa and a 60 KDa glycoprotein in the organic matrix of $N$. anomala. Two glycoproteins with molecular weights of 67 KDa and 62 KDa have also been isolated from the prismatic layer of the oyster Crassostrea virginica (Kawaguchi and Watabe, 1993), while Pinnes et al., (1995) identified the glycoprotein osteopontin in the eggshell of the domestic fowl. The common occurrence of glycoproteins in calcium carbonate biominerals suggests that the carbohydrate groups may be involved in shell formation possibly via their negatively charged sulphate and carboxylic acid groups.

Proteoglycans such as mammillan, a keratan sulphate proteoglycan (Nys et al., 1999), ovoglycan, a dermatan sulphate proteoglycan (Fernandez et al., 2001) and glycosaminoglycans such as chondroitin-4-sulphate and dermatan sulphate have been identified in the eggshell of the domestic fowl (Carrino et al., 1997 and Nys et al., 1999). Glycosaminoglycans, and the extent to which they are sulphated, exert control over the morphology and number of calcite crystals grown in vitro (Arias et al., 2002). The addition of dermatan sulphate exerts control over the morphology of calcite crystals nucleated both in vitro (Arias et al. 2002) and on eggshell mammillae (Fernandez et al., 2004) resulting in crystals with a columnar morphology. Kawaguchi and Watabe (1993) found evidence to suggest that glycosaminoglycans contained within the soluble organic matrix of the oyster Crassostrea virginica surrounded the surfaces of the calcite crystals of the shell and were also in close contact with glycosaminoglycans contained within the insoluble organic matrix component. The presence of glycosaminoglycans such as chondroitin sulphate and keratan sulphate in the shells of the molluscs Pinna nobilis and Pincatada margaritifera has also been highlighted (Dauphin et al., 2003a and Dauphin et
al., 2003b). Analysis of the interprismatic walls of both Pinna and Pinctada by X-ray absorption near-edge structure spectroscopy (XANES) revealed the presence of a high concentration of sulphate (indicative of the presence of sulphated sugars) within the organic matrices. The role of these sulphated sugars in the biomineralisation process has also been supported by in vitro studies of the interaction of organic matrix macromolecules with calcium carbonate crystals (Kitano and Hood, 1965, Addadi et al., 1987 and Wu et al., 1994).

### 4.3 Results

### 4.3.1 Concentration and Distribution of Organic Matrix

The concentration of organic material in the shells of T. retusa, N. anomala, M. edulis Gallus gallus was determined by Loss on Ignition (LOI) as described in Section 2.7.1. The results presented in Table 4.1 are an average of three sets of analyses.

| Biomineral | \% Organic Content <br> (range) | \% Organic Content <br> (average) |
| :---: | :---: | :---: |
| T. retusa Ventral Valve | $2.34-2.68$ | 2.48 |
| T. retusa Dorsal Valve | $2.36-3.11$ | 2.62 |
| N. anomala Dorsal Valve | $4.46-5.76$ | 5.05 |
| M. edulis calcite | $1.58-1.69$ | 1.64 |
| M. edulis aragonite | $3.19-3.23$ | 3.21 |
| Avian Eggshell | $2.25-5.21$ | 3.73 |

## Table 4.1 Loss on Ignition Results

The organic content of the shells of T. retusa, N. anomala, M. edulis and G. gallus was determined using Loss on Ignition (Section 2.7.1). The results presented are the range and mean values of three sets of analyses.

The backscattered electron signal increases with the mean atomic number the density of the material being analysed. As such, electron backscatter imaging can be used to highlight differences of atomic number of a sample. Biominerals are organic/inorganic
composites therefore electron backscatter imaging should highlight the difference in atomic number between areas with a high organic content (low mean atomic number) and areas with a high mineral content (high mean atomic number).

Figure 4.1 presents backscattered electron images of the shells of $T$, retusa, N. anomala, M. edulis and Gallus gallus within which the lighter areas have the greater mean atomic number.

The backscatter image of T. retusa (Figure 4.1a) shows that the primary layer has a greater mean atomic number than the secondary layer. If spatial variations in the proportion of backscattered electrons does reflect the relative proportions of mineral and organic matrix then it is possible to determine the distribution of organic material in each system as follows: the secondary layer of $T$. retusa has a higher organic content than the primary layer of the shell. In $N$. anomala the central section of the secondary layer contains a higher concentration of organic matrix than the outer and inner portions of the shell. The aragonite layer of M. edulis has a higher organic content than the calcite layer of the shell. However, alternating bands of high/low density material are apparent in the outer portion of the calcite layer. In G. gallus the concentration of organic matrix is high in the mammillary caps but decreases across the zone where the mammillary caps fuse. The organic content increases in the outer portion of the eggshell.

Figure 4.1 Backscattered electron images of T. retusa, N. anomala, M. edulis and the G. gallus

Backscattered electron images were produced as described in Section 2.7.2. White/light grey areas are composed of material with a higher mean atomic number than areas that are dark grey such as organic matrix. (a) T. retusa, (b) N. anomala, (c) M. edulis and (d) G. gallus

### 4.3.2 Molecular Weight of Intercrystalline and Intracrystalline Proteins

The intercrystalline and intracrystalline organic matrix fractions of T. retusa, N. anomala and M. edulis were extracted as described in Section 2.8.1 and Section 2.8.2 respectively. For $G$. gallus only the intracrystalline fraction was extracted by incubation of the sample in EDTA (Section 2.8.2), as the extraction of the intercrystalline proteins by incubation of the sample in GnHCL (Section 2.8.1) affects the intracrystalline protein extract and the final resolution of the proteins by SDS PAGE. The proteins from both the intercrystalline and intracrystalline fractions were separated by SDS PAGE (Section 2.8.4) and visualised using the staining techniques described in Section 2.8 .6 and Section 2.8.7. Sample volumes and gel loadings are presented in Appendix C.

Three proteins of 47,38 and 15 kDa from the intercrystalline protein fraction of $T$. retusa and a 38 kDa protein from the intracrystalline fraction were separated by SDS PAGE (Figure 4.2).

Figure 4.2 Silver stained, $15 \%$ polyacrylamide gel of the intercrystalline and intracrystalline protein fractions of $T$. retusa

Intercrystalline and intracrystalline protein extracts of T. retusa were prepared as described in Section 2.8. The proteins were electrophoresed on a Biorad ${ }^{T M}$ minigel system at 60 V . Lane 1 Mid range protein standards (Section 2.8.4). Lane 2 Soluble intercrystalline protein extract. Lane 3 Soluble intracrystalline protein extract. Lanes 4 Mid range protein standards (Section 2.8.4).

Proteins with molecular weight of 63 kDa and 58 kDa are present in both the intercrystalline and intracrystalline extracts of $N$. anomala (Figure 4.3). Three proteins with apparent molecular weights of $43 \mathrm{kDa}, 35 \mathrm{kDa}$ and 13 kDa are also present in the intracrystalline protein extract.

Figure 4.3 Silver stained, 15\% polyacrylamide gel of the intercrystalline and intracrystalline protein fractions extracted from $N$. anomala

Intercrystalline and intracrystalline protein extracts of N . anomala were prepared as described in Section 2.8. The proteins were electrophoresed on a Biorad $^{T M}$ minigel system at 60 V . Lane 1 Mid range molecular weight protein standards (Section 2.8.4). Lane 2 Soluble intercrystalline protein extract. Lane 3 Soluble intracrystalline protein extract. Lanes 4 and 5 Prestained low range protein standards (Section 2.8.4).

A number of proteins with molecular weights ranging between 26 kDa to 81 kDa are present in the intercrystalline extract of M. edulis (Figure 4.4). Two proteins of 35 kDa and 26 kDa are present in both the intercrystalline and intracrystalline protein fractions. It is difficult to resolve other protein bands in the intracrystalline extract due to the smear of material in the gel.

Extrapallial fluid was extracted from samples of M. edulis as described in Section 2.2. The fluid extract was washed with Milli $Q^{\mathrm{TM}}$ and concentrated through a Microcon 10 kDa filter as described in Section 2.2. Proteins in the resultant fluid sample were separated by SDS PAGE and the proteins fixed and visualised by incubation in Coomassie Brilliant Blue as described in Section 2.8.5. The extrapallial fluid of M. edulis contains two proteins with molecular weights of 33 kDa and 30 kDa (Figure 4.5).

Figure 4.4 Silver stained, $15 \%$ polyacrylamide gel of the intercrystalline and intracrystalline protein fractions of M. edulis

Intercrystalline and intracrystalline protein extracts of M . edulis were prepared as described in Section 2.8. The proteins were electrophoresed on a Biorad ${ }^{T M}$ minigel system at 60 V . Lane 1 Mid range molecular weight protein standards (Section 2.8.4). Lane 2 Soluble intercrystalline protein extract. Lane 3 Soluble intracrystalline protein extract. Lanes 4 Mid range protein standards (Section 2.8.4).

Figure 4.5 Coomassie Blue stained, 20\% polyacrylamide gel of protein within the extrapallial fluid of M. edulis

Extrapallial fluid extracted from specimens of M . edulis was prepared as described in Section 2.2. The extract was electrophoresed on a Biorad ${ }^{T M}$ minigel system at 60 V . Lane 1 and 2 Prestained low range molecular weight protein standards (Section 2.8.4). Lane 3 and 4 Extrapallial fluid extract from M. edulis. Lane 5 and 6 Mid range protein standards (Section 2.8.4).

Only the intracrystalline protein fraction was extracted from the avian eggshell as extraction of the intercrystalline organic matrix by incubation of the powdered mineral sample in GnHCL affects the intracrystalline matrix and the resolution of the proteins by gel electrophoresis. The intracrystalline organic matrix of the avian eggshell contains a number of proteins with molecular weights ranging from 16 kDa upto 70 kDa (Figure 4.6).

Figure 4.6 Silver stained, $15 \%$ polyacrylamide gel of eggshell (Gallus gallus) intracrystalline protein

Intracrystalline proteins extracted from the avian eggshell were prepared as described in Section 2.8. The proteins were electrophoresed on a Biorad ${ }^{T M}$ minigel system at 60 V . Lane 1 Mid range molecular weight protein standards (Section 2.8.4). Lane 2, 3 and 4 Soluble intracrystalline protein extract.

### 4.3.3 Protein Charge

The intracrystalline proteins extracted from the shells of T. retusa, N. anomala, M. edulis (calcite and aragonite) and G. gallus were fractionated on the basis of their charge by isoelectric focusing (Section 2.8.8). The proteins were then visualised by incubation of the gel in Coomassie Brilliant Blue Stain. The isoelectric points of the intracrystalline proteins extracted from T. retusa, N. anomala, M. edulis and the avian eggshell range between approximately 3.5-7 indicating that they are acidic (Figure 4.7).

Figure 4.7 Intracrystalline proteins separated by isoelectric focusing
Intracrystalline proteins extracted from T. retusa, N. anomala, M. edulis (calcite and aragonite) and G. gallus were prepared as described in Section 2.8. Low PI standard proteins (Section 2.8.5) are to the left of lane 1. High PI standard proteins (Section 2.8.5) are to the right of Lane 9. Lane 1 and 2=M. edulis aragonite intracrystalline proteins, Lane 3 and $4=$. edulis calcite intracrystalline proteins, Lane $5=$ G. gallus intracrystalline proteins, Lane $6=$ Total mussel proteins (i.e. calcite and aragonite), Lane $7=$ T. retusa intracrystalline proteins, Lane 8 and $9=N$. anomala intracrystalline proteins. Protein samples were loaded at different positions within each lane.

### 4.3.4 Organic Sulphate

The location of sulphur in the shells of T. retusa, N. anomala, M. edulis and G. gallus cannot be distinguished by electron microprobe analysis alone as this technique does not determine the phase that is analysed. In order to determine if organic sulphate is associated with the intercrystalline and intracrystalline organic matrix of T. retusa, $N$. anomala, M. edulis and G. gallus proteins were fractionated by SDS PAGE (Section 2.8.4) and stained with Acridine Orange in accordance with the technique described by Dauphin et al. (2003a), (Section 2.8.7).

Proteins extracted from the intercrystalline and intracrystalline organic matrix fractions of T. retusa stain in Coomassie Brilliant Blue and silver stain (Figure 4.2). These protein bands are not discernable when stained with Acridine Orange (Figure 4.8). Only larger matrix molecules extracted from the intercrystalline material stain faintly in Acridine Orange, while the intracrystalline extract of T. retusa appears as a smear of material in the gel.

## Figure 4.8 Acridine Orange stained, 15\% polyacrylamide gel of T. retusa intercrystalline and intracrystalline protein fractions

Intercrystalline and intracrystalline proteins from T. retusa were prepared as described in Section 2.8. The proteins were electrophoresed on a Biorad ${ }^{T M}$ minigel system at 60 V and visualised by staining with Acridine Orange (Dauphin et al., 2003). Lane 1 Prestained low molecular weight protein standards (See Section 2.8.4). Lane 2 Soluble intercrystalline protein extract. Lane 3 Soluble intracrystalline protein extract.

When stained with Coomassie Brilliant Blue and silver stain a number of proteins extracted from the intercrystalline and intracrystalline organic matrix fractions of $N$. anomala are apparent within the gel (Figure 4.3). When stained with Acridine Orange however only a smear of material larger than 44 kDa is visualised (Figure 4.9).

| kDa | 1 | $2 \boldsymbol{T}$ |
| :--- | :--- | :--- |
| 44 |  |  |
| 29 |  |  |
| 20 |  |  |
| 14 |  |  |
| 5 |  |  |
| 2 |  |  |

Figure 4.9 Acridine Orange stained, $15 \%$ polyacrylamide gel of $N$. anomala intracrystalline protein fraction

The intracrystalline protein extract of N . anomala was prepared as described in Section 2.8. The proteins were electrophoresed on a Biorad ${ }^{T M}$ minigel system at 60V (Section 2.8.4) and visualised by staining with Acridine Orange (Dauphin et al., 2003). Lane 1 Prestained low molecular weight protein standards (See Section 2.8.4). Lane 2 Soluble intracrystalline proteins.

When separated by gel electrophoresis and the gel stained with Coomassie Brilliant Blue and silver stain the intracrystalline extract of M. edulis appears as a smear in the gel. However, some proteins are discernable (Figure 4.4). When stained with Acridine Orange the intracrystalline material again appears as a smear in the gel while low molecular weight material, less than 14 kDa is heavily stained (Figure 4.10).

| $\mathrm{kDa} \quad \mathrm{l}$ |  |
| :---: | :---: |
| 44 |  |
| 29 |  |
| 20 |  |
| 14 |  |
| 5 |  |
| 2 |  |

Figure 4.10 Acridine orange stained, $10 \%$ polyacrylaminde gel of $M$. edulis intracrystalline fraction

The intracrystalline protein extract of M . edulis was prepared as described in Section 2.8. The proteins were electrophoresed on a Biorad ${ }^{T M}$ minigel system at 60 V (Section 2.8.4) and visualised by staining with Acridine Orange (Duaphin et al., 2003). Lane 1 Prestained low molecular weight protein standards (See Section 2.8.4). Lane 2 Soluble intracrystalline protein extract.

A number of proteins extracted from the intracrystalline organic matrix of the eggshell of G. gallus are visualised in Coomassie Brilliant Blue and silver stain (Figure 4.6). However, when stained with Acridine Orange the intracrystalline appears as a smear in the gel (Figure 4.11).

Figure 4.11 Acridine orange stained, $15 \%$ polyacrylamide gel of G. gallus eggshell intracrystalline protein fraction

The intracrystalline protein extract of the avian eggshell was prepared as described in Section 2.8. The proteins were electrophoresed on a Biorad ${ }^{T M}$ minigel system at 60 V and visualised by staining with Acridine Orange. Lane 1 Prestained low molecular weight protein standards (See Section 2.8.4). Lane 2 Soluble intracrystalline protein extract.

### 4.3.5 Distribution of Amino Acids in T. retusa, N. anomala, M. edulis and G. gallus

The distribution of amino acids between the intercrystalline and intracrystalline protein fractions of T.retusa, N. anomala, M. edulis and G. gallus was determined by amino acid analysis. Samples were manually hydrolysed (Section 2.9.1) and analysed using an Applied Biosystems $420-\mathrm{H}$ analyser (Section 2.9.2). Figure 4.12 displays the concentration of amino acids in the total, intercrystalline and intracrystalline protein fractions. Intact valves were cleaned and rinsed using sodium hypochlorite ( $1 \% \mathrm{v} / \mathrm{v}$ ) as described in Section 2.2. Cleaned valves were powdered using a ceramic mortar and pestle (Section 2.9.1). The total concentration of amino acids was extracted by dissolving the powder in an aqueous solution of HCL ( 2 N ). The solution was transferred to hydrolysis tubes and dried under vacuum. The tubes were placed in vials containing $500 \mu \mathrm{l} \mathrm{HCl}(6 \mathrm{~N})$, purged with argon, sealed and heated at $165^{\circ} \mathrm{C}$ for one hour (Section 2.9.1). Treatment of shell powder with sodium hypochlorite ( $1 \% \mathrm{v} / \mathrm{v}$ ) (Section 2.9.1) destroyed the intercrystalline amino acids therefore only intracrystalline amino acids were extracted upon dissolution of the sodium hypochlorite-treated shell powder (Section 2.9.1). The concentration of intercrystalline amino acids was the difference between the total and intracrystalline amino acid concentration.

Considering the concentration of amino acids in each of the systems in turn, for T. retusa the overall concentration of amino acids is greater in the ventral valve, while the concentration of amino acids is slightly higher in the intercrystalline fraction in relation to the intracrystalline fractions in both valves. In the dorsal valve of $N$. anomala there is an even distribution of amino acids between the intercrystalline and intracrystalline protein fractions. The concentration of amino acids is greater in the left valve of M. edulis, while the concentration of amino acids is greater in the intercrystalline protein fraction in relation to the intracrystalline protein fraction in both valves. In G. gallus the distribution of amino acids is highest in the intracrystalline protein fraction.

Between the four systems the dorsal valve of $N$. anomala has the lowest total concentration of amino acids, while G. gallus has the highest total concentration. The dorsal valve of $N$. anomala has the lowest concentration of intercrystalline amino acids, while M. edulis has the highest concentration of intercrystalline amino acids. The right valve of M. edulis has
the lowest concentration of intracrystalline amino acids, while G. gallus has the highest concentration of intracrystalline amino acids (Figure 4.12).

Figure 4.12 Distribution of amino acids in T. retusa, N. anomala, M. edulis and an avian eggshell (Gallus gallus)

Powdered shell samples were incubated in an aqueous solution of sodium hypochlorite ( $1 \% \mathrm{v} / \mathrm{v}$ ) as described in Section 2.9.1. Total, inter and intracrystalline amino acids were extracted (Section 2.9.1) and the amino acid concentration determined (Sections 2.9.2 and 2.9.3).

One-letter codes for amino acids are presented in Table 4.2. The relative abundances of amino acids (displayed as amino acids per hundred residues) in the total, intercrystalline and intracrystalline protein fractions of T. retusa, N. anomala, M. edulis and G. gallus are presented in Tables 4.3-4.8, and Figures 4.1-4.15. In all cases, the total protein and intercrystalline protein extracts have a high glycine content. The intracrystalline fractions of T. retusa, N. anomala and M. edulis are also glycine rich. The total protein fraction of T. retusa also has a relatively high content of asparagine/aspartic acid, arginine, alanine and valine. The total protein fraction of the dorsal valve of N. anomala has a high concentration of asparagine/aspartic acid, alanine and proline. The total protein composition of both valves of M. edulis includes a high alanine and lysine content. The total protein fraction of the eggshell is enriched in alanine and lysine. However, overall the amino acid composition is more balanced than in the marine biominerals.

The intercrystalline fraction of $T$. retusa has a similar composition to the total protein fraction and is enriched in asparagine/aspartic acid, valine and alanine. The intercrystalline fraction of $N$. anomala is enriched in proline, alanine and asparagine/aspartic acid. The intercrystalline protein fraction of $M$. edulis has a similar composition to the total protein fraction and is enriched in alanine and lysine, while the intercrystalline fraction of the eggshell is proline rich.

The intracrystalline protein fraction of both valves of $T$. retusa is rich in glycine and valine, while the dorsal valve protein fraction is also enriched in proline. The intracrystalline protein fraction extracted from the dorsal valve of $N$. anomala is enriched in glycine, asparagine/aspartic acid and serine. The intracrystalline protein from the right valve of $M$. edulis is enriched in proline, threonine, glycine and serine, while the left valve is enriched in glycine, proline and alanine. The intracrystalline protein fraction of G. gallus is enriched in serine, histidine, tyrosine, threonine and isoleucine.

Figure 4.13 Amino acid composition of the total protein fraction of $T$. retusa, $N$. anomala, M. edulis and G. gallus

Samples were prepared and hydrolysed as described in Section 2.9.1. The total amino acid composition was determined as described in Section 2.9.2. Values are presented as amino acids per 100 residues using the one-letter codes for amino acids (Table 4.2).

Chapter 4 Organic Matrix Composition

Figure 4.14 Amino acid composition of the intercrystalline protein fraction of T. retusa, N. anomala, M. edulis and G. gallus

Samples were prepared and hydrolysed as described in Section 2.9.1. The intercrystalline amino acid composition was estimated from the concentration of amino acids destroyed by incubation in sodium hypochlorite. Values are presented as amino acids per 100 residues using the one letter codes for amino acids (Table 4.2).

Figure 4.15 Amino acid composition of the intracrystalline fraction of T. retusa, N. anomala, M. edulis and G. gallus

Samples were prepared and the intercrystalline matrix fraction destroyed as described in Section 2.9.1. Samples were hydrolysed as described in Section 2.9.1. The intracrystalline amino acid composition was determined as described in Section 2.9.2. Values are presented as amino acids per 100 residues using the one letter code for amino acids (Table 4.2)

### 4.3.6 N -Terminal Sequencing

Intracrystalline proteins extracted from the shells of $T$. retusa and $N$. anomala were transferred to a Problott Membrane using a Biorad Mini Transblot Electrophoretic Transfer Cell as described in Section 2.10.1. N-terminal sequencing of the most abundant protein $(38 \mathrm{kDa})$ from the organic matrix of $T$. retusa and the 35 kDa protein from the matrix of $N$. anomala was undertaken as described in Section 2.10.2. The 38 kDa protein of $T$. retusa could not be sequenced as the N -terminal of the protein was blocked preventing the Edman Degradation Chemistry. The N-terminal sequence of the 35 kDa protein of $N$. anomala is shown below:

### 4.3.7 Calcite Growth in the Presence of Intracrystalline Proteins

Calcite crystals were grown in vitro according to the Kitano protocol (Kitano, 1962), (Section 2.11.1). A control experiment was carried out in which the crystals were allowed to develop over 24,48 and 72 hours in the absence of additives. As the intracrystalline protein extracts are buffered by sodium phosphate buffer the effect of buffer on the development of the crystals was assessed by the addition of $2 \mu \mathrm{~L}$ of sodium phosphate buffer to the crystal growth solution.

The method for analysis of crystal size was modified from Roque et al., (2004). Images of the coverslips on which the crystals were grown were taken using an SEM. The magnification for each image was kept constant, therefore the area of each coverslip covered by the image was consistent. The number of crystals and the area of each crystal within the whole image were assessed using the computer software Scion Image. Histograms of crystal number and size were produced using the statistical package SPSS.

Crystals grown in solution without additives were calcite. Crystals grown in the presence of sodium phosphate buffer were also calcite, but were malformed and often present in clusters (Figure 4.18 b). As a result all intracrystalline protein extracts were washed thoroughly with Milli $Q^{\mathrm{TM}}$ through microcon filters to remove the sodium phosphate buffer.

Figure 4.16 presents histograms of the number and size of crystals which developed over 24,48 and 72 hours both with and without the addition of sodium phosphate buffer. The highest total number of crystals ( N ) was formed after 48 hours, however the overall difference between $N$ for 24 and 48 hours was relatively small. In each experiment the sodium phosphate buffer had an inhibitory effect on calcite crystal growth.

Crystals that were grown with the addition of intracrystalline proteins were left to develop over 24 and 48 hours. Figure 4.17 presents histograms of the number and size of crystals grown in the presence of intracrystalline extracts of T. retusa, N. anomala, M. edulis and the eggshell over 24 hours. The concentration of protein added to each crystal growth experiment is presented in Table 2.4 (Chapter 2, Section 2.11.2). The addition of $T$. retusa intracrystalline organic matrix extract does not appear to have an inhibitory effect on calcite growth at a concentration of $1.6 \mathrm{ng} / \mathrm{ml}$. N. anomala and M. edulis intracrystalline extracts, and to some extent M. edulis extrapallial fluids had an inhibitory effect on calcite growth. It should be noted that the concentration of protein in the intracrystalline extracts that were added to the calcite growth solution varied due to the small concentration of protein that was available and therefore these results are preliminary.

Figure 4.18 displays representative examples of crystal morphology. Crystals that developed over 48 hours in the solution without additives commonly displayed a rhombohedral habit with well defined crystal faces (Figure 4.18a), while secondary crystal growth is also common. Crystals grown in the presence of T. retusa intracrystalline organic matrix extract for 48 hours show pitted surfaces and evidence of clustering (Figure 4.18 c ). With the addition of intracrystalline organic matrix extract from $N$. anomala the calcite crystals displayed evidence of a layered structure with the secondary growth of small rhombohedral calcite crystals on the surface of the crystal (Figure 4.18d and e). The addition of intracrystalline organic matrix extracted from the shell of $M$. edulis to the saturated calcium carbonate solution resulted in the formation of globular shaped precipitates (Figure 4.18f). Crystals grown with the addition of M. edulis extrapallial fluid display rounded edges and there is also evidence of crystal clustering and secondary crystal growth (Figure 4.18 g ). With the addition of eggshell intracrystalline organic matrix the crystals display a layered structure with pitted surfaces (Figure 4.18 g and h ). X-ray diffraction analysis confirmed that crystals that were grown in the presence of intracrystalline extracts of $T$. retusa, $N$. anomala, and the eggshell and extrapallial fluid extracted from M. edulis are composed of calcite. However, XRD analysis indicates that
the crystals grown in the presence of $M$. edulis intracrystalline organic matrix extract are amorphous (Figure 4.19).

## Figure 4.16 Histograms of Crystal Number vs. Crystal Size for calcite growth in vitro

Calcite crystals were grown on coverslips according to the Kitano Protocol (Section 2.11.1). Coverslips were removed from the saturated calcium carbonate solution after 24, 48 and 72 hours. Sodium phosphate buffer was added to samples $d$, e and $f$ at the start of crystallisation. (a) 24 hours, (b) 48 hours, (c) 72 hours, (d) 24 hours with buffer, (e) 48 hours with buffer and (f) 72 hours with buffer. SEM images of the coverslip were acquired (at a constant magnification) and the number of crystals and the area of the image that each crystal covered analysed using the computer software Scion Image. Histograms were produced using the statistical package SPSS.

Figure 4.17 (a-d) Histograms of Crystal number vs. Crystal Size for calcite growth with the addition of intracrystalline proteins

Calcite crystals were grown on coverslips according to the Kitano Protocol (Section 2.11.1). Coverslips were removed from the saturated calcium carbonate solution after 24 hours. Intracrystalline organic matrix extract from (a) T. retusa, (b) N. anomala, (c) M. edulis and (d) Extrapallial fluid from M. edulis. SEM images of the coverslips were acquired (at a constant magnification) and the number of crystals and the area of the image that each crystal covered analysed using the computer software Scion Image. Histograms were produced using the statistical package SPSS.

Figure 4.18 ( $\mathbf{( - i}$ ) Scanning electron micrographs of calcite crystals after 48 hours growth with addition of intracrystalline organic matrix extracts

Calcite crystals were grown according to the Kitano Protocol (Kitano, 1962), (Section 2.11.1) with the addition of intracrystalline organic matrix extracts (Section 2.11.2) and prepared for SEM analysis (Section 2.11.2). (a) No extract added (control), (b) Addition of $2 \mu \mathrm{l}$ of sodium phosphate buffer. (c) Addition of T. retusa intracrystalline extract. (d) Addition of N . anomala intracrystalline extract and (e) Addition of N . anomala intracrystalline extract. (f) Addition of
M. edulis intracrystalline extract, (g) Addition of M. edulis extrapallial fluid extract. (h) Addition of eggshell intracnstalline extract and (i) Addition of eggshell intracnstalline extract.

Figure 4.19 X-ray Diffraction pattern from crystals grown in the presence of $\boldsymbol{M}$. edulis intracrystalline proteins

Crystals were grown on coverslips according to the Kitano Protocol (Kitano, 1962) (Section 2.11.1). Intracrystalline protein extracted from M. edulis shell (Section 2.8.2) was added to the saturated calcium carbonate solution. Coverslips were removed from the saturated calcium carbonate solution after 48 hours. XRD analysis was carried out using a Phillips PW 1050/35 X-ray diffractometer (Section 2.3).

### 4.4 Discussion

### 4.4.1 Intercrystalline and intracrystalline organic matrix composition

By comparing the composition of organic matrix from these four different carbonate biominerals, we can to some extent, determine if there are any common principles that underlie the biomineralisation process. The characterisation of the organic matrix composition and the crystal ultrastructure of biominerals from different species may also shed light on the relationship between the organic matrix composition and crystal morphology. This study has characterised proteins extracted from the shells of $T$. retusa, N. anomala, M. edulis and G. gallus in relation to their molecular weight and charge and the overall amino acid composition of the total, intercrystalline and intracrystalline organic matrix extracts. The relationship between the organic matrix and sulphate has also been investigated as it is recognised that sulphated polysaccharides within the matrix may also have a role in the mineralisation process (Dauphin, 2003, Miyashita et al., 2000 and Yang et al., 2003).

### 4.4.1.1 Comparison of the intercrystalline and intracrystalline organic matrix of $\boldsymbol{T}$. retusa, N. anomala, M. edulis and the avian eggshell (G. gallus)

The intercrystalline and intrarystalline organic matrix extracts of T. retusa, N. anomala, M. edulis and G. gallus contain proteins of relatively low molecular weight.

The intercrystalline and intracrystalline protien fractions of $T$. retusa contain a protein with a molecular weight of 38 kDa , which stains in silver nitrate. A less abundant protein with a molecular weight of 47 kDa has also been identified in the intercrystalline protein fraction. A more abundant 39 kDa protein and a 45 kDa protein were identified from the intracrystalline organic matrix by Laing (1999), while Cusack et al., (2000) identified a relatively abundant 40 kDa protein in the intracrystalline protein fraction of $T$. retusa. The 39 kDa protein described by Laing and the 40 kDa protein described by Cusack et al., (2000) are likely to be the same protein as the 38 kDa protein that has been identified in this study.

The intracrystalline organic matrix of $N$. anomala contains a relatively abundant 35 kDa protein. Two proteins with molecular weights of 63 kDa and 58 kDa were identified in both the intercrystalline and intracrystalline protein fractions. The 35 kDa protein identified in
the intracrystalline protein fraction was not seen in the intercrystalline protein fraction. Brown (1998) identified a 44 kDa protein and a less abundant 60 kDa protein in the intracrystalline fraction of $N$. anomala, while Cusack et al., (2000) identified a main protein of 40 kDa from the intracrystalline fraction. Again this is likely to be the same protein as the 35 kDa protein described here and the difference in estimated molecular weight is due to errors in estimating protein molecular weight from polyacrylamide gels (Section 4.3.2). The 63 kDa and 58 kDa proteins described here may also be related to the 60 kDa protein described by Brown (1998). The difference in resolution of the proteins may be related to the difference in acrylamide content of the polyacrylamide gels used for the protein separation (i.e. $15 \%$ polyacrylamide gels were used for protein separation in this study). As the 35 kDa protein is present only in the intracrystalline fraction this suggests that it has a different function in the mineralisation process in relation to the 63 kDa and 58 kDa proteins, which are present in both the intercrystalline and intracrystalline fractions.

Two proteins of 35 kDa and 26 kDa are present in both the intercrystalline and intracrystalline protein fractions of $M$. edulis. The intercrystalline protein fraction contains a number of proteins with molecular weights ranging up to 81 kDa . A number of matrix proteins have been isolated from the shells of bivalve molluscs. Lustrin A, a framework protein with a molecular weight of 65 kDa , has been identified in the shell of the marine gastropod Haliotis rufescens (Shen et al., 1997), while Samata et al., (1999) isolated a family of matrix proteins, N16 ( 16 kDa ) from the nacreous layer of the oyster, Pinctada fucata. Soluble mollusc shell matrix proteins include nacrein with a molecular weight of 60 kDa (Miyashita et al., 1996), and perlucin ( 17 kDa ) and perlustrin ( 13 kDa ) extracted from the shell of Haliotis laevigata.

The intracrystalline extract from the avian eggshell (Gallus gallus) contains proteins with a wide molecular weight range. A number of eggshell organic matrix proteins have been identified. Ovalbumin (Hincke, 1995), lysozyme and ovotransferrin (Gautron et al. 1997) occur at organic nucleation sites on the eggshell membrane. Proteins that have been extracted and characterised from the domestic fowl eggshell include Ovocleidin-17 (Hincke et al., 1995), which has a molecular weight of 17 kDa , Ovalbumin ( 45 kDa ) (Hincke, 1995), lysozyme (15kDa) (Gautron et al., 1997), ovocalyxin-32 (32kDa) (Gautron et al., 2001), ovotransferrin ( 80 kDa ) (Gautron et al., 1997). The larger molecule ovocleidin-116 (Mann et al., 2002) is present in two forms, a core protein without attached
glycosaminoglycans, which has a molecular weight of $116-120 \mathrm{kDa}$ and as a proteoglycan with a molecular weight of $180-200 \mathrm{kDa}$.

The total amino acid extracts of T.retusa, N. anomala, M. edulis and G. gallus are all enriched in glycine. The total protein extract of the brachiopods T. retusa and N. anomala are enriched in asparagine/aspartic acid. The eggshell has the lowest asparagines/aspartic acid content of the four systems but has a higher concentration of glutamine/glutamic acid. The total protein extract of $M$. edulis differs from the protein extract from the two brachiopods in that it is enriched in both alanine and leucine. The total extract of T. retusa and the avian eggshell are both enriched in valine, while the protein extract from $N$. anomala and the avian eggshell are both enriched in proline.

The intercrystalline extract of T. retusa, N. anomala, M. edulis and G. gallus are all glycine rich. As for the total protein extracts, the avian eggshell has the lowest concentration of glycine of the four systems and has a higher concentration of glutamine/glutamic acid. $T$. retusa and $N$. anomala are enriched in asparagine/aspartic acid, while $N$. anomala and M. edulis are both enriched in leucine.

Fibrous proteins that are rich in glycine and alanine have been identified as a major component of the EDTA insoluble organic matrix of molluscs (Miyashita et al., 2000). Weiner and Traub (1980) suggest that these fibrous proteins provide the organic matrix framework core as proposed in the template model for molluscan organic matrix. Sudo et al., (1997) isolated two framework proteins from the shell of Pinctada fucata. Protein MSI 60 is enriched glycine and alanine while protein (MSI 31) is rich in glycine and glutamic acid. The intercrystalline fraction of M. edulis is also slightly more enriched in alanine than the intracrystalline fraction which may be explained by the presence of glycinealanine rich framework proteins. Hare (1963) described a high glycine, alanine and aspartic acid content from the organic matrix of Mytilus californianus. The overall amino acid composition and the ratio of acidic to basic residues extracted from M. californianus also differed between the calcite and aragonite layers. The difference in amino acid composition between the left and right valves of $M$. edulis may therefore be explained by differences in the ratio of calcite:aragonite between the two valves.

The intracrystalline protein fraction of T. retusa, N. anomala, M. edulis and G. gallus are all glycine rich. The intracrystalline fraction of $N$. anomala is asparagine/aspartic acid rich, while G. gallus is glutamine/glutamic acid rich. N. anomala and M. edulis contain
high concentrations of serine, while M. edulis contains a high concentration of proline. The avian eggshell is enriched in threonine and leucine.

EDTA-soluble organic matrices extracted from a variety of invertebrate skeletons have a high content of acidic amino acids, in particular aspartic acid (Section 4.2.4). As discussed in Section 4.2.4 aspartic acid residues may have a calcium binding function and may therefore have an important role in skeletal formation. The template model described by Weiner and Hood (1975) suggests that the presence of proteins in $\beta$-sheet conformation with repeat sequences of the type (Asp-Y) ${ }_{n}$ where $Y$ is commonly glycine or serine results in a repetitive negative charge and as such may determine the arrangement of $\mathrm{Ca}^{2+}$ ions on the matrix surface. Acidic proteins with calcium binding properties have also been extracted from the organic matrix of the eggshell of the domestic fowl. Cortivo et al (1982) identified a low molecular weight protein with calcium binding property that was related to the aspartic acid and glutamic acid residues.

The amino acid composition of T. retusa, N. anomala, M. edulis and the eggshell show some similarities e.g. all are enriched in glycine. However, there are also differences in composition i.e. the marine systems all have a relatively high asparagine/aspartic acid content while the eggshell is enriched in glutamic acid. In all cases the proteins are acidic as confirmed by isoelectric focusing (Section 4.3.3). There are similarities in amino acid composition between species from the same phylum i.e. $T$. retusa and $N$. anomala. However, there are also similarities between the brachiopods and the bivalve mollusc, $M$. edulis. The similarities in amino acid composition between N. anomala and M. edulis are of particular interest due to the similarity in crystal ultrastructure. N. anomala produces calcite semi-nacre while M. edulis produces a layer of aragonite nacre. Similarities in amino acid composition may therefore be indicative of matrix proteins with similar functions in the development of the mineral ultrastructure.

Weiner and Traub (1984) proposed the template model for the composition of molluscan organic matrix in which the core of the organic matrix layers are composed of a silk-fibroin-like protein which is covered on both surfaces by layers of soluble matrix components with calcium-binding properties. The amino acid data presented here suggests that the intercrystalline organic matrix extracted from M. edulis is slightly more enriched in glycine than the intracrystalline organic matrix fraction. Weiner and Hood (1975) found that the soluble organic matrix of the molluscs Crassostrea virginica, Mercenaria mercenaria, Crassostrea irredescens and Nautilus pompilius were enriched in glycine and
aspartic acid. However, the concentration of alanine is lower than that reported in this study and by Hare (1963) for M. californianus. The high glycine content of T. retusa and N. anomala is in common with the high glycine content identified in the shells of other brachiopod species (Walton, 1992) and suggests that proteins with repeat sequences containing glycine may also be components of the organic matrix in these biomineral systems. However, little information is available on the amino acid sequences of proteins extracted from the organic matrices of brachiopods. Brown (1998) determined the N terminal sequence of a 44 kDa protein from the shell of $N$. anomala, which has been confirmed by this study (Section 4.3.6).

### 4.4.2 Organic Matrix Carbohydrate

When separated by SDS-PAGE, intracrystalline proteins extracted from the organic matrix stain in Coomassie Brilliant Blue and silver stain (Section 4.3.2). However, these protein bands do not stain in Acridine Orange (Section 4.3.4). Dauphin et al., (2003a) suggest that the Acridine Orange staining technique is sensitive to acidic sulphated sugars such as chondrotin sulphate, which stains easily with acridine orange, while proteins such as bovine serum albumin do not stain with Acridine Orange.

The intracrystalline extracts from the T. retusa, N. anomala, M. edulis and G. gallus all stain in Acridine Orange indicating the presence of acidic sulphated sugars. The sulphated acidic sugar, chondroitin sulphate is associated with the soluble organic matrices of the bivalve molluscs Pinna and Pinctada (Dauphin et al., 2003a and Dauphin, 2003). Glycosaminoglycans such as dermatan sulphate and chondroitin sulphate have also been identified in the organic matrix of the eggshell (Nys et al., 1999 and Arias et al., 1992), while Arias et al., (2002) presented evidence of the effect of glycosaminoglycan concentration on the nucleation and morphology of calcite crystals in vitro. The presence of acidic sulphated sugars in the soluble organic matrices extracted from $T$. retusa, $N$. anomala, M. edulis and G. gallus suggests that these macromolecules may have an important role in biomineralisation which is not yet completely understood.

Electron microprobe analysis of minor elements does not determine the phase in which the element is present. EPMA of the minor element concentration of $T$. retusa (Section 3.3.1.2) indicates that sulphur displays a positive covariation with magnesium, strontium and sodium. The intercrystalline and intracrystalline organic matrix of $T$. retusa and the intracrystalline organic matrix extracts of $N$. anomala, M. edulis and the avian eggshell all
stain in Acridine Orange indicating the presence of acidic sugars with associated sulphate $\left(\mathrm{SO}_{4}\right)$, (Dauphin et al., 2003a). This suggests that a proportion of the sulphur analysed by electron microprobe may be associated with the organic matrix. The correlation between sulphur and magnesium, strontium and sodium suggests that some of these elements may be associated with the organic phase as well as the mineral phase. In the case of $N$. anomala minor element analyses indicate that sulphur does not correlate with other elements suggesting that, in $N$. anomala the minor elements are not associated with the organic matrix. Sulphur correlates with strontium and sodium in the calcite layer of $M$. edulis but does not correlate with magnesium. The differences in correlation between sulphur and other minor elements between the four biominerals may be the result of differences in the composition and structure of the organic matrix macromolecules. The exact location of these ions within the biomineral cannot be confirmed however, and more work is needed to establish if minor elements are associated with the mineral or organic phase in these biomineral systems.

### 4.4.3 Influence of intracrystalline proteins on crystal growth

Organic matrix proteins extracted from biomineral systems have been found to influence the nucleation, morphology and polymorph of calcium carbonate crystals in vitro (Wheeler et al., 1988, Weiss et al., 2000, Gautron et al., 1996, Belcher et al., 1996 and Falini et al., 1996).

In this case the addition of intracrystalline extract from N. anomala and M. edulis to a saturated calcium carbonate solution inhibited the growth of calcite in vitro. The addition of intracrystalline extract from T. retusa did not inhibit calcite growth. Laing (1998) found that as the concentration of $T$. retusa protein extract added to the calcite crystal growth solution increased the number of calcite crystals formed decreased. In this case the concentration of $T$. retusa protein added to the crystal growth solution was low in comparison to the concentration of protein in extracts of $N$. anomala, M. edulis and M. edulis extrapallial fluid. At higher concentrations the addition of $T$. retusa soluble organic matrix may inhibit calcite formation.

The addition of soluble organic matrix proteins from molluses also induces crystal nucleation (Roque et al., 2004 and Weiss et al., 2000). The addition of M. edulis acidic organic matrix proteins induced the nucleation of calcite and vaterite crystals in vitro (Roque et al., 2004). In this case the product of the addition of M. edulis soluble matrix
proteins to a calcium carbonate growth solution was amorphous. It should be noted however that the difference in results between in vitro crystallisation experiments might in part be due to the different methods used for calcium carbonate crystallisation in vitro.

The addition of intracrystalline organic matrix from each system and extrapallial fluid from M. edulis also influenced crystal morphology (Figure 4.18). The morphology of crystals grown in the presence of protein extracts from each system varied. In the presence of $T$. retusa intracrystalline protein, crystals were present as clusters and displayed pitted surfaces. The addition of protein extracted from $N$. anomala produced small crystals that displayed secondary growth on the surface. With the addition of M. edulis organic matrix the crystals were amorphous while the extrapallial fluid extract produced crystal clusters. The addition of eggshell intracrystalline proteins produced smaller crystals with a layered structure. Due to the low quantity of protein available these experiments are preliminary and should be replicated to confirm the results.

## Chapter 5 Discussion and Further Work

### 5.1 Aims of the Study

This study aimed to consider the extent to which calcium carbonate biominerals that are distinct in appearance are of similar composition. The minor element and organic matrix composition, in particular the protein component of the shells, of three marine invertebrates and an avian eggshell have been characterised in order to compare their components. The biomineral systems include an articulated brachiopod Terebratulina retusa, an inarticulated brachiopod Novocrania anomala, and the bivalve mollusc Mytilus edulis, and a fourth outlying system, the eggshell of the domestic fowl, Gallus gallus. Together they comprise a range of ultrastructures and two types of calcium carbonate polymorph: calcite and aragonite. G. gallus is formed under very different environmental conditions than the marine biominerals.

The following chapter summarises the main findings of this study and discusses the biomineral components and mineralisation processes involved in the formation of each system. For detailed results and discussion on individual topics the reader is referred to the appropriate chapter. Chapter 3 outlines the distribution of minor elements within the context of the ultrastructure and polymorph type of the mineral phase. Chapter 4 details the molecular weight, charge and amino acid composition of intercrystalline and intracrystalline proteins extracted from the four systems. The carbohydrate content of the organic matrix and its role in the biomineralisation process is also discussed in Chapter 4.

### 5.2 The Four Biomineral Systems

The brachiopods, T. retusa and $N$. anomala were collected from the same location at a depth of 200 m in the Firth of Lorne off the coast of Oban, NW Scotland. Specimens of $T$. retusa and $N$. anomala have developed under the same environmental conditions i.e. water temperature and salinity, throughout ontogeny. The bivalve M. edulis although also taken from a marine environment is likely to have been subjected to different environmental conditions to the two brachiopods as it is found in shallower water in which there are greater fluctuations in temperature and salinity. In contrast to the
marine systems the eggshell is formed rapidly i.e. approximately 3 g of calcite is deposited within 24 hours, in a controlled constant temperature environment.

### 5.2.1 Mineral Ultrastructure and Polymorph Type

The shell of $T$. retusa consists of an outer primary layer composed of acicular calcite with a thicker underlying secondary layer of calcite fibres (Figure 3.1). The shell of $N$. anomala also comprises two layers; a thin primary layer of acicular calcite and a secondary layer composed of calcite semi-nacre (Figure 3.12). Mytilus edulis shell is composed of two calcium carbonate polymorphs, calcite and aragonite. The outer layer of the shell is prismatic calcite while the inner layer is composed of aragonite nacre (Figure 3.23). The calcite eggshell of the domestic fowl comprises six regions (Figure 3.33). The inner shell is lined with an organic membrane upon which initial crystal nucleation takes place forming the mammillary caps. The mammillary caps eventually fuse and are overlain by the palisade layer and the vertical crystal layer, which comprises calcite columns aligned perpendicular to the palisade layer. The outer cuticle is composed of organic material and hydroxyapatite crystals (Dennis et al., 1996).

### 5.3 Minor Element Concentration and Distribution in

## Relation to Mineral Ultrastructure

In Chapter 3, the distribution of the minor elements, magnesium, sulphur, sodium, strontium and in some instances, phosphorus is discussed in context of the mineral ultrastructure. Any relationships between crystal ultrastructure and minor element composition can therefore be determined.
$\mathrm{Mg} / \mathrm{Ca}$ ratio in the shells of marine invertebrates has mainly been of interest due to its potential as a palaeoseawater thermometer (Watannabe et al., 2000, Lear et al., 2002, Lear et al., 2000). Analysis of shell chemistry may also provide clues as to the processes involved in biomineralisation (Lowenstam and Weiner, 1989). In the four systems discussed here, magnesium is present at different concentrations and displays a variety of distribution patterns. T. retusa and $N$. anomala were collected from the same location, yet $T$. retusa produces a low magnesium calcite shell, (Section 3.3.1.2) while N. anomala produces a high magnesium calcite shell, (Section 3.3.2.2). This suggests that differences in magnesium concentration between the two brachiopods reflect
biological rather than environmental factors. In the shell of T. retusa, the greatest concentration of magnesium is found in the primary layer and decreases across the primary/secondary layer boundary (Figure 3.6). Within the secondary layer there is also a decrease in magnesium concentration from the outer to the inner part of the secondary layer (Figure 3.6b). In $N$. anomala, magnesium concentrations across both the primary and secondary layers of the shell are relatively invariant and there is no significant difference in overall magnesium concentrations between the primary and secondary layers (Figure 3.17 and Table 3.4). The patterns of magnesium distribution in T. retusa and $N$. anomala therefore show that ultrastructure is not the main determinant of variations in shell chemistry in these brachiopods. In M. edulis, concentrations of magnesium in each layer are determined by the calcium carbonate polymorph present. Owing to similarities in ionic size and charge, $\mathrm{Mg}^{2+}$ can substitute for $\mathrm{Ca}^{2+}$ in the calcite lattice. However, it substitutes less readily for $\mathrm{Ca}^{2+}$ in the more open orthorombic lattice of aragonite. Therefore, magnesium concentration is consistently higher in the calcite than aragonite layer of M. edulis. There is variation in magnesium distribution within the calcite layer of M. edulis and the distribution pattern can vary between individuals (Figure 3.29). Magnesium concentration in the eggshell changes as the ultrastructure changes. The eggshell displays a high concentration of magnesium in the mammillary caps, which are formed at the start of lay but decreases across the zone in which the mammillary caps fuse and then increases gradually through the palisade layer and vertical crystal layer to the cuticle. However the abrupt change from the palisade layer to the vertical crystal layer is not apparent in magnesium concentration, which changes gradually from the inner to the outer shell surface.

It has been suggested that incorporation of $\mathrm{Mg}^{2+}$ into calcite is related to growth rate (Major and Wilber, 1991, Burton and Walter, 1987). At slow growth rates the mineral system has time to equilibrate and thus discriminate against ions such as $\mathrm{Mg}^{2+}$. In contrast fast growth rates result in a higher rate of substitution of $\mathrm{Mg}^{2+}$ for $\mathrm{Ca}^{2+}$. The results of this study suggest that, although this may apply to some biotic systems (Buenning and Carlson, 1992), it does not apply to others. The primary layer of $T$. retusa is formed quickly and has a higher concentration of magnesium than the secondary layer. The overall concentration of magnesium decreases from the primary layer through the secondary layer to the inner surface of the $T$. retusa shell in correspondence with a decline in growth rate throughout ontogeny (Curry, 1982). This supports the suggestion that growth rate influences the concentration and distribution of
magnesium. If a physical process such as precipitation rate is the principal influence on the concentration of magnesium in calcite it might be expected that it would influence magnesium concentration in all calcite biomineral systems. However, N. anomala is a slow growing brachiopod with a shell composed of high magnesium calcite (Ruggiero, 2001). While the bivalve M. edulis secretes its shell faster than the brachiopod T. retusa it has a lower concentration of magnesium in the calcite layer of the shell than that found within the shell of T. retusa. In the case of the eggshell, growth rate may have an influence on the uptake of magnesium but further work is required to determine the precipitation rate of the calcite during various stages of eggshell formation.

Temperature may also exert a control over the $\mathrm{Mg} / \mathrm{Ca}$ and $\mathrm{Sr} / \mathrm{Ca}$ values of calcium carbonate (Rosenthal et al., 1997, Lea et al., 1999, Beck et al., 1992). There is an exponential relationship between seawater temperature and the concentration of magnesium in the skeletons of marine invertebrates including benthic foraminifera (Rosenthal et al., 1997, Nurnberg et al., 1997 and Lea et al., 1999), while an exponential relationship has also been found in some species of recent articulated brachiopod (Lowenstam, 1961, Lowenstam and Weiner, 1989). The relationship between strontium concentration and seawater temperature in the shells of articulated and inarticulated brachiopods differed. In articulated brachiopods strontium is positively correlated with temperature, whereas the shells of inarticulated brachiopods (Craniidae) show a negative correlation (Lowenstam and Weiner, 1989). A negative correlation between $\mathrm{Sr} / \mathrm{Ca}$ and temperature is also found in aragonite coral skeletons (Beck et al., 1992).

Samples of $T$. retusa and $N$. anomala studied here grew in the same environment but have significantly different concentrations of magnesium within their shells. Therefore, temperature cannot be the main control on magnesium incorporation into the calcite shells of these brachiopods. Temperature is also not the primary control on magnesium incorporation in the avian eggshell. The eggshell is formed in a constant temperature environment yet has a range of Mg concentrations. Even though results of this study demonstrate temperature is not the principal control on magnesium incorporation in the four systems studied, the role of temperature in determining the uptake of magnesium into marine calcite biominerals cannot be dismissed. Finer resolution analyses combined with detailed environmental data would be needed to determine if there is an underlying correlation between temperature and magnesium/strontium concentration.

Spatial variations in minor and trace element concentration of the shell of M. edulis have been related to spatial variation in metabolic activity of the mantle (Rosenberg et al. 1991). Areas of the shell that are rich in minor elements and organic matrix are metabolically expensive to produce and are therefore linked to the areas of the mantle that have a high metabolic activity (Rosenberg et al., 1991). Although this hypothesis cannot be confirmed by results of this study, the impact of metabolic activity on shell chemistry should not be ignored. The marginal mantle of T. transversa, which produces the primary and upper secondary layers of the shell, has a higher metabolic activity than the posterior mantle which produces the lower secondary layer (Rosenberg et al. 1988 and Auclair et al. 2003). If these variations in mantle metabolic activity are also present in $T$. retusa then areas of the shell that are relatively rich in minor elements i.e. the primary and upper secondary layers are secreted by mantle with a high metabolic activity. Differences in the physiology and biomineralisation mechanisms of molluscs and brachiopods make it difficult to make comparisons between the two phyla. More work is required on the metabolism of brachiopods and its role in determining shell composition and development.

If extant marine invertebrates are passive in relation to the uptake of elements from seawater, it would be expected that they will produce high magnesium calcite skeletons reflecting present high marine $\mathrm{Mg} / \mathrm{Ca}$ values (Stanley et al., 2002 and Hardie, 1996). Stanley et al., (2002) suggest that this is indeed the case for simple organisms such as algae in which the composition of the biomineral appears to change with variations in solution composition. Therefore, modern marine invertebrates that produce low magnesium calcite skeletons such as M. edulis must employ physiological mechanisms for the exclusion of magnesium (Lorens and Bender, 1977 and Nurnberg et al. 1996). However, the brachiopod $N$. anomala produces a high magnesium calcite skeleton. Lowenstam and Weiner (1989) found that the trace element content of the shells of inarticulated brachiopods (Craniidae) is in equilibrium with the seawater. As this is not the case for the trace element content of articulated brachiopod shells it suggests that inarticulated brachiopods such as $N$. anomala do not have the same physiological mechanisms in place to exclude magnesium from their tissues.

Variations in chemistry across the shell of G. gallus (Section 3.3.4.2) may simply be related to changes in the composition of the uterine fluid from which the shell precipitates. The pattern of magnesium, sodium, potassium and phosphorus
concentration throughout the eggshell appears to correlate with the concentration of these elements in the uterine fluid as reported by Arad et al., (1989) and Nys et al., (1991 and 1999), (Section 3.4.3).

The influence of magnesium ions on the morphology of carbonate crystals (Meldrum and Hyde, 2001 and Loste et al., 2003), and the effect of magnesium on calcite precipitation rate have been established (Hincke and St. Maurice, 1998). Hincke and St. Maurice (1998) found that the addition of magnesium to a calcium carbonate crystal growth solution accelerated the onset of calcite precipitation but inhibited the maximum rate of precipitation with respect to the control experiment. The addition of phosphate ions also inhibited the maximum rate of calcite precipitation. If the chemical composition of the eggshell is related to the composition of the uterine fluid then changes in ionic composition of the uterine fluid during lay may be a fundamental mechanism for controlling calcite precipitation rates and crystal morphologies of $G$. gallus shells.

There are good correlations between the concentrations of certain chemical elements within the four systems. In $T$. retusa and the calcite layer of $M$. edulis, strontium displays a positive correlation with sodium (Figure 3.8 and Figure 3.30). Determining the location of $\mathrm{Na}^{+}$within the calcite lattice is difficult as sodium is monovalent and therefore not expected to substitute for $\mathrm{Ca}^{2+}$. It is possible that $\mathrm{Na}^{+}$sits in interstitial spaces in the lattice. If this is the case, the substitution of the larger $\mathrm{Sr}^{2+}$ ion for $\mathrm{Ca}^{2+}$ in the calcite lattice may result in lattice defects due to the differences in ionic size into which $\mathrm{Na}^{+}$can be accommodated. In the calcite layer of M. edulis, strontium and sodium both correlate positively with sulphur, while magnesium, strontium and sodium display a positive correlation with sulphur in the shell of $T$. retusa. If sulphur is associated with the organic matrix, as has been found in molluscs such as Pinna and Pinctada (Dauphin et al., 2003a), then the correlation between sulphur and other elements suggests that these elements are also associated with the organic matrix in both T. retusa and M. edulis (Section 3.4.1 and Section 3.4.2).

There are no good correlations between elements in the shell of $N$. anomala (Figure 3.18). As sulphur does not correlate with any of the other elements this suggests that elements are not associated with the organic matrix and are accommodated within the lattice. The difference in lattice structure of high magnesium calcite and low
magnesium calcite may also explain some differences in element concentration between N. anomala and T. retusa. However, the principal differences in element concentration between the two brachiopods probably relate to differences in physiology (Section 3.4.1).

### 5.4 Minor Element Distribution in Relation to the Distribution of Organic Matrix

Sulphur is a good measure of the distribution of organic matrix within calcium carbonate biominerals (Dauphin et al., 2003a, Lorens and Bender, 1980). In the shell of T. retusa, sodium, strontium and magnesium all correlate positively with sulphur, while in the calcite layer of M. edulis sodium and strontium positively correlate with sulphur. However, this trend is not evident in the high Mg-calcite shell of $N$. anomala.

Sulphur is present in the shells of the molluscs Pinna and Pinctada predominantly as sulphate associated with the organic matrices (Dauphin et al., 2003a). Lorens and Bender (1980) and Vander Putten et al., (2000) suggest that sulphur may be associated with the organic matrix of $M$. edulis. Organic matrices extracted from T. retusa, N. anomala, M. edulis and G. gallus all stain with Acridine Orange, which indicates the presence of acidic sulphated sugars (Dauphin et al., 2003a). In each system sulphur is associated with the organic component of the shell (Section 4.3.4), therefore correlation between sulphur and other elements may indicate that these elements are also associated with the organic matrix.

Magnesium and sodium may be present in the aragonite skeleton as $\mathrm{MgSO}_{4}$ and $\mathrm{NaSO}_{4}{ }^{-}$ and are not associated with the organic matrix in significant concentrations (Mitsuguchi et al., 2001). The association of magnesium and sodium with $\mathrm{SO}_{4}$ in the mineral phase in the shells of $T$. retusa and M. edulis cannot be dismissed.

### 5.5 Organic Matrix Composition

The organic matrix of T. retusa, N. anomala, M. edulis and the avian eggshell, all contain small, acidic proteins as confirmed by gel electrophoresis (Section 4.3.2) and isoelectric focusing (Figure 4.7). The presence of acidic proteins in the soluble organic matrix is a common factor in calcium carbonate biominerals. These acidic proteins may
have a calcium-binding function in the biomineralisation process (Weiner et al. 1983, Weiner and Hood, 1975, Weiner and Traub, 1984). The role of these acidic matrix components in controlling the nucleation, morphology and crystal stucture of the mineral has also been confirmed by in vitro studies (Albeck et al., 1993, Belcher et al. 1996, Greenfield and Crenshaw, 1989, Falini et al. 1996, Feng et al. 2000). The soluble organic matrix of the marine invertebrates T. retusa, N. anomala and M. edulis are all acidic as confirmed by isoelectric focusing (Section 4.3.3), while the organic matrix of the marine invertebrates is enriched in aspartic acid with respect to the eggshell which has a higher content of glutamic acid. Even though the organic matrix macromolecules display some similarities i.e. they are all acidic, they show some differences in terms of their overall amino acid composition. The three marine invertebrates are enriched in aspartic acid with respect to the eggshell which has a higher concentration of glutamic acid while $M$. edulis is enriched in alanine with respect to the other three systems. However, all four systems have a high glycine content. Fernandez et al., (2004) noted that there are insufficient similarities between the amino acid sequences of eggshells and seashells to indicate that they have common mechanisms for regulating crystal growth.

The carbohydrate component of the organic matrix may also have an important role in biomineralisation. The organic matrix of T. retusa, N. anomala, M. edulis and G. gallus all contain sulphated sugars (Section 4.3.4). Glycosaminoglycans have also been found in the organic matrices of the molluscs, Pinna and Pincatada (Dauphin et al. 2003a) and the avian eggshell (Nys et al., 1999). The common occurrence of sulphated sugars such as chondroitin sulphate and dermatan sulphate in the organic matrices of calcium carbonate biominerals suggests that these macromolecules may be involved in the biomineralisation process.

### 5.6 Calcium Carbonate Biomineralisation in Disparate Systems- Common Mechanisms?

The four calcium carbonate biomineral systems differ in appearance, ultrastructure and in some cases crystal structure i.e. M. edulis. The minor element composition of the shells of T. retusa, N. anomala, M. edulis and G. gallus do not clearly correspond with differences in ultrastructure. Contrasts in minor element composition between the two brachiopods are possibly to be related to differences in physiology. In particular, the fact that $T$. retusa has a low magnesium calcite shell while $N$. anomala has a high
magnesium calcite shell suggests that $N$. anomala lacks the ability to exclude magnesium from its tissues, a physiological mechanism that is prevalent in organisms which secrete low magnesium calcite skeletons in present day aragonite seas. In $M$. edulis crystal structure is the principal determinant of the distribution of minor elements. Metabolic processes and fluctuations in environmental conditions (i.e. temperature and salinity) may also influence the chemical composition of the shell (Rosenberg and Hughes, 1991 and Vander Putten et al., 2000). The incorporation of minor elements into the shell of G. gallus is similar to that of $N$. anomala in being related to the passive uptake of elements from the mineralising medium. However in the case of G. gallus, the ionic composition of the uterine fluid is regulated, which suggests that ions such as $\mathrm{Mg}^{2+}$ and $\mathrm{P}^{+}$may have an active role in the growth and development of the shell. It is also possible that elements such as magnesium are associated with the organic matrix in some biomineral system, for example T. retusa and M. edulis. Differences in the structure and composition of the matrix macromolecules may therefore be reflected in the association of these elements with sulphur (i.e. sulphated macromolecules in the organic matrix). In conclusion, the results of this study suggest that there may be similarities between some calcium carbonate biomineral systems such as metabolic influence on shell chemistry and the ability to control the ionic composition of the mineralising medium, but there is not an underlying mechanism that controls the inorganic shell chemistry in all four systems.

The proteins extracted from the shells of T. retusa, N. anomala, M. edulis and G. gallus are small (Section 4.3.2) and all are acidic (Section 4.3.3). The amino acid compositions of the four systems display similarities and differences (e.g. all have a high glycine content), while the eggshell differs from the shells of T. retusa, N. anomala and M. edulis in that glutamic acid is present in higher concentration than aspartic acid.

All four systems contain sulphated sugars (Section 4.3.4). Arias and Fernandez (2003) and Dauphin et al., (2003) also recognised a common occurrence of sulphated macromolecules (proteoglycans) in the eggshell and marine invertebrate shells, which suggests that these macromolecules may have an important role in the formation of calcium carbonate biominerals.

The organic components of the shells of T. retusa, N. anomala, M. edulis and G. gallus display some superficial biochemical similarities which suggest that there are common
underlying mechanisms involved in the interaction of the organic matrix with the biomineral, however in detail the protein profiles from each system are ultimately different.

### 5.7 Suggestions for Further Work

Future work on the minor and trace element composition of these four systems should aim to determine whether individual elements are coordinated with the organic matrix or are present within the mineral lattice. Detailed analyses of the shell crystal structure using Electron Backscatter Diffraction (EBSD) together with high-resolution chemical maps produced by Scanning X-ray Microscopy (XANES) may shed light on this problem. In the case of the marine systems trace element data might also be correlated with environmental conditions e.g. temperature and salinity in order to determine the effect of environmental variations on the uptake of elements into the shells. Electron microprobe analyses of the G. gallus eggshell indicate that variations in the minor and trace element composition of the shell may be related to changes in uterine fluid composition. Detailed work should therefore be undertaken to establish if shell chemistry is primarily a function of the composition of the uterine fluid.

Cathodoluminescence spectroscopy is a new technique for the study of biominerals. Further development of this method could provide a powerful tool for the analysis of carbonate biomineral composition. In particular, correlation of the wavelengths of luminescence emitted in relation to the distribution of elements within a system would provide a method for detailed chemical analysis.

Little work has been undertaken on the amino sequence of proteins within the organic matrix of brachiopods. This has hindered attempts to determine whether these proteins display homology with other biomineralisation proteins. An attempt should be made therefore to determine the amino acid sequences of these proteins. This may also be of use in evolutionary studies.

Detailed crystal growth experiments with the addition of proteins extracted from the four systems should be undertaken with the addition of different protein concentrations.

## Appendix A

## Materials

## Item

Milli $Q^{\text {TM }}$ water
Guanidine hydrochloride
Tris buffer
Benzamidine- HCl
N-ethylmalcimide
Phenyl methyl sulphonyl fluoride
Sodium Phosphate
Ethylene diamine tetra acetic acid (EDTA)
Minitan ${ }^{\text {TM }}$ Tangential Flow Ultrafiltration System
Centriprep ${ }^{T M}$ Concentrators
Microcon ${ }^{\text {TM }}$ Concentrators
Acrylamide/bisacrylarnide (40\% solution)
Ammonium persulphate (APS)
Tetramethylethane (TEMED)
Sodium dodecyl sulphate (SDS)
Glycerol
$\beta$-Mercaptoethanol
Bromophenol Blue
Unstained Proteins of known molecular weight
Full range proteins of known molecular weight
Low Molecular weight protein standards
Coomassic Brilliant Blue
Methanol
Acetic Acid
Dithiothreitol
Silver nitrate
Sodium Ten Decahydrate
Formaldehyde
Acridine Orange
HydrochloricAcid (Amino acid analysis)
$\mathrm{K}_{3}$ EDTA
Polyvinylidine fluoride (Problott) Membrane
CAPS buffer
Ethanol
Calcium carbonate
Carbon dioxide

## Appendix C Gel Protein Data

## SDS Polyacrylamide Gel Loadings

Terebratulina retusa (Figure 4.2)

|  | Concentration (mg/ $\mu \mathrm{l})$ | Loading $(\mu \mathrm{l})$ |
| :---: | :---: | :---: |
| Lane 1 | Unstained protein standards | - |
| Lane 2 | T. retusa GnHCL extract | 204 |
| Lane 3 | T. retusa EDTA extract | 228 |

Novocrania anomala (Figure 4.3)

|  | Concentration (mg/ $\mu \mathrm{l})$ | Loading ( $\mu \mathrm{l})$ |
| :---: | :---: | :---: |
| Lane 1 Unstained protein standards | - | 5 |
| Lane $2 \quad$ N. anomala GnHCl extract | 73 | 10 |
| Lane3 $\quad$ N. anomala EDTA extract | 63 | 10 |

## Mytilus edulis (Figure 4.4)

|  | Concentration (mg/ $\mu$ ) | Loading ( $\mu \mathrm{l}$ ) |
| :---: | :---: | :---: |
| Lane 1 | Unstained protein standards | - |
| Lane 2 | M. edulis GnHCL extract | 541 |
| Lane 3 | M. edulis EDTA extract | 208 |

## Gallus gallus (Figure 4.6)

|  | Concentration (mg/ $\mu \mathrm{l})$ | Loading $(\mu \mathrm{l})$ |
| :---: | :---: | :---: |
| Lane 1 Unstained protein standards | - | 5 |
| Lane 2,3\&4Eggshell EDTA extract | 171 | 10 |
