Abstract

Two parasitic trypanosomatids, *T. b. gambiense* and *T. b. rhodesiense*, are responsible for around 150,000 death a year by Human African Trypanosomiasis (HAT). Prevalence values in some villages reaches up to 50%, making HAT the leading cause of mortality. There are currently only four drugs available for treating HAT, but problems with availability, administration, disease stage specificity and severe side effects have hindered their uses.

The most used drug is the arsenical, Melarsoprol, but resistance is increasingly reported in the field. Some reports have suggested that point mutations within the *TbAT1*, encoding the P2 transporter, were associated with drug resistance in both laboratory-derived strains and field isolates. However, analysis of a *ΔTbAT1* cell showed a low level of resistance and 50% of field isolates had a non-mutated P2 transporter. Consequently, it seems likely that multiple mechanisms can confer a resistance phenotype but these have been largely undescribed to date.

The advantage of a global proteomic expression profiling study of drug sensitive and drug resistant isogenic *T. brucei* lines is that, in principle, all possible mechanisms could be identified without pre-supposing a specific mechanism. The release of an almost complete *T. brucei* genome database, the advances in 2DE technology and mass spectrometry techniques, and the availability of drug sensitive and resistant isogenic *T. brucei* lines rendered this analysis feasible.

Subtractive analysis of the whole proteome of the drug sensitive and resistant isogenic line of STIB 386 identified two proteins whose loss of expression was associated with Cymelarsan resistance. Cymelarsan is a drug that is structurally and functionally closely related to Melarsoprol. Tandem mass spectrometry analysis matched the first protein onto either open reading frame (ORF) 274 or 277, present as identical tandem repeats on chromosome IX. This protein spot was shown to be an isoform of a spot located a similar molecular weight but with a more basic pI. As both ORFs have identical predicted amino acid sequences, are transcribed and no other homologues were found in the *T. brucei* genome, it is likely that the missing protein is an isoform of the adjacent protein which arose due to a post-translational modification. I have named this protein the Cymelarsan Associated Resistance (CAR) protein. The absence of the protein was not associated with Cymelarsan resistance in a pair of isogenic drug sensitive and resistant lines of 247.
The second protein spot associated with Cymelarsan resistance was identified as an arginine kinase from either ORF 342 or 343. These two ORF, present as tandem repeat on chromosome IX are not identical. However, the degree of sequencing obtained from the Tandem mass spectrometry analysis did not enable to differentiate between product of each ORF.

Finally, a diminished reduction of the Alamar Blue dye was found associated with Cymelarsan resistance in both pairs of isogenic lines analysed. An attempt was made to determine the mechanism that impaired the reduction of the Alamar blue dye in the drug resistant lines. The transport and efflux of the dye were analysed and did not account for the difference in reduction of the Alamar Blue dye. The dye was found to concentrate in vesicle-like structures thought to be acidocalcisomes.

Acknowledgements

Firstly, I would like to thanks my supervisors, Dr. Mike Turner, Dr. Jonathan Wastling and Prof. Andy Tait for their supervision, suggestions and support throughout the 3 years of my PhD.

I would also like to thank the Wellcome Trust for its financial support during the tenure of my PhD.

Thanks to all the people who have indirectly contributed to this PhD, to my friends in North lab and North/West lab who have been brilliant to work with.

I am especially grateful to Chris Wards for some useful (as well as completely useless) conversations, and for sharing the particularly difficult time of "gel pouring" with me.

I am grateful for the invaluable help and advice received from Dr Mike Barrett, Dr Sharon Kelly, Dr Richard Burchmore, Dr Gill Douce, Dr Andy Pitt, Dr Keith Mattews and Mrs Anne McIntosh.

Je tiens tout particulierement a remercier ma famille pour le soutient morale, la patience et l'amour qu'ils m'ont abondament donnee pendant toutes ces annees. Cette these n'aurais pu avoir lieu sans eux.

Chapter I
General introduction

1.1 Trypanosomes

1.1.1 Introduction

1.1.1.1 Current status of Human African Trypanosomiasis (HAT)

The latest data published by the World Health Organisation (WHO, 2003) indicate that 300,000 people suffer currently from HAT, and a further 50 million people in sub-Saharan Africa are at risk of infection. In 1996, 150,000 people died and 100,000 were handicapped by the disease and in the same year 30,000 new cases were reported. In 1998, 45,000 new cases were reported (Barrett, 1999). Sixty million people, living in 36 sub-Saharan countries (22 of which are among the poorest countries in the world) are under the daily threat of contracting HAT (Figure 1.1). Only four million of them have access to diagnosis and treatment.

There are at least 200 foci of HAT in sub-Saharan Africa and a resurgence of trypanosomiasis is occurring in the Democratic Republic of Congo (Van Nieuwenhove *et al.*, 2001), the Central African Republic (Smith *et al.*, 1998), Uganda (Olila *et al.*, 2002), Sudan (Moore and Richer, 2001) and Angola (Stanghellini and Josenando, 2001). Prevalence rates reach up to 50% in some villages, making HAT the leading cause of mortality. In two provinces of the Democratic Republic of Congo the number of deaths due to HAT have been estimated to be equal to or higher than the number of deaths due to Acquired Immune Deficiency Syndrome (AIDS) (WHO, 2003).

In addition, resistance to Melarsoprol, the drug of first choice for the treatment of HAT, has been reported in many epidemic areas of Africa. The overall relapse rate over the past 50 years was of 5 - 8% (Pepin and Milford,1994), but this rate has risen to 25% in Angola (Stanghellini and Josenando, 2001) and 30% in Uganda (Legros *et al.*, 1999) in recent years.

The increase in prevalence and distribution of HAT associated with the increase in drug resistance reported cases have initiated new research interests in the discovery of the mechanisms of drug resistance to the existing drugs and the development of new treatment for HAT.

1.1.1.2 Taxonomy/Classification

African trypanosomes are flagellated parasitic protozoa belonging to the order kinetoplastidae and the family trypanosomatidae. Kinetoplast flagellates are characterised by the possession of a unique organelle called the kinetoplast which contains deoxyribonucleic acid (DNA) and is an integral part of the mitochondrial system.

The genus *Trypanosoma* is classically subdivided into two groups of infective parasites, the stercorarian trypanosomes and the salivarian trypanosomes. In the stercorarian trypanosomes, the flagellates divide in the hind gut of the insect vector and metacyclic forms are passed out with the faeces. The most important species is *T. cruzi* which infects 12 to 24 million people in South and Central America. The disease it causes is called Chagas' disease and the most serious clinical consequences of infection are cardiac failure due to the presence of the parasite in the heart muscles or the loss of nervous control of the alimentary tract due to the presence of the parasites in the nervous system. In contrast to

the stercorarian trypanosomes, the salvarian trypanosomes typically develop in the mid gut of the vector and either in the salivary glands (*T. brucei*) or the mouthparts (*T. vivax* and *T. congolense*). One of the major species of salivarian trypanosomes is *T. brucei* which is divided into three subspecies *T. b. brucei*, *T. b. rhodesiense* and *T. b. gambiense*. These three subspecies are morphologically identical, but can be distinguished by isoenzyme analysis and restriction enzyme fragment length polymorphism (RFLP) (Gibson, 2002; Kanmogne *et al.*, 1996; Truc and Tibayrenc, 1993). *T. b. brucei* primarily infects cattle, goats, and sheep; *T. b. gambiense* is distributed in West and Central Africa and causes Western African HAT; and *T. b. rhodesiense* in Eastern and Southern Africa is the cause of Eastern African HAT (Figure 1.1) (Wang, 1995). Only two taxonomic groups of tsetse flies commonly transmit the flagellate protozoan parasite that causes HAT. The *palpalis* group is the chief carrier of *T. b. gambiense* and the *morsitans* group is the chief carrier of *T. b. rhodesiense*. There are several species within the palpalis group and within the morsitans group. Other species of salivarian trypanosomes *T. congolense* and *T. vivax* are the causative agent of Nagana, a trypanosomiasis in domesticated animals. Several species of *Glossina* transmit *T. congolense* and *T. vivax*.

Molecular phylogenetic analysis of the Trypanosoma, undertaken by sequencing the 18S RNA genes of 31 different species and subspecies, showed the existence of three distinct clades (Stevens *et al.*, 1999). The *T. brucei* clade consists of the salivarian tsetse transmitted trypanosomes from Africa. *T. evansi* and *T. equiperdum*, although non-tsetse transmitted and not restricted to Africa, also belong here by virtue of their close morphological and genetic similarity with *T. brucei*. Importantly, this clade is characterised by the expression of a dense variable surface glycoprotein coat (VSG coat) in the bloodstream forms of the parasite (section 1.1.2). The variability lies in the fact that

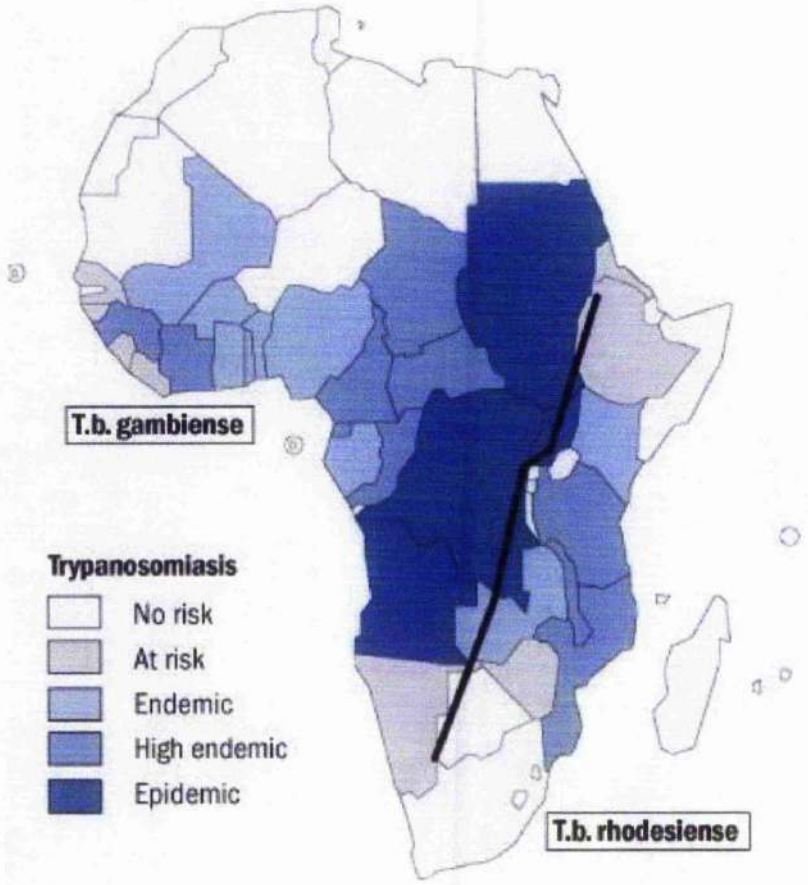

Figure 1.1: Geographic distribution of Human African Trypanosomiasis. The black line represents the approximate division for the distribution *of T. b. gambiense* and *T. b. rhodesiense*. Reproduced from medilinks.org/Features/Articles/june2002/tryps.htm

the parasite can change its VSG coat by switching between expression of multiple VSG genes, a process called antigenic variation (Barry and McCulloch, 2001). This process enables the parasite to evade the host immune response. The *T. cruzi* clade originates mainly from South American mammals, with some interesting exceptions: two species of European bat trypanosomes and one as yet unnamed species of kangaroo trypanosome from Australia. Finally, an aquatic clade comprising trypanosome species isolated from both marine and fresh water fish and amphibian has been observed (Stevens *et al*, 1999). Interestingly, the molecular phylogenetic analysis agreed with the classical classification of the Trypanosoma species.

1.1.2 Life cycle

Parasites of the *T. brucei* group are transmitted from the tsetse fly to their mammalian host where they replicate first in the bloodstream, lymphatic system and interstitial spaces, and then, during the latter stages of the infection in the central nervous system. In the mammal the bloodstream trypanosomes multiply as "long slender" forms by binary fission and eventually differentiate into a non-dividing "short stumpy" forms. The bloodstream trypanosomes have the ability to evade the host immune system by antigenic variation. A diagram of the life cycle of *T. brucei* is shown in Figure 1.2, which includes some of the intermediate forms that have been previously described (Vickerman, 1985). Trypanosomes are ingested by the tsetse fly (*Glossina* spp.) when a blood meal is taken (Vickerman, 1965). Once the short, stumpy trypomastigote reaches the mid-gut of the tsetse fly, it transforms into a long, slender procyclic form. The parasites multiply in the lumen of the midgut by binary fission. After approximately two weeks, the parasites migrate to the salivary glands through the hypopharynx, where the parasites attach to the epithelial cells of the salivary glands and then transform to the epimastigote form (Evans and Ellis, 1983).

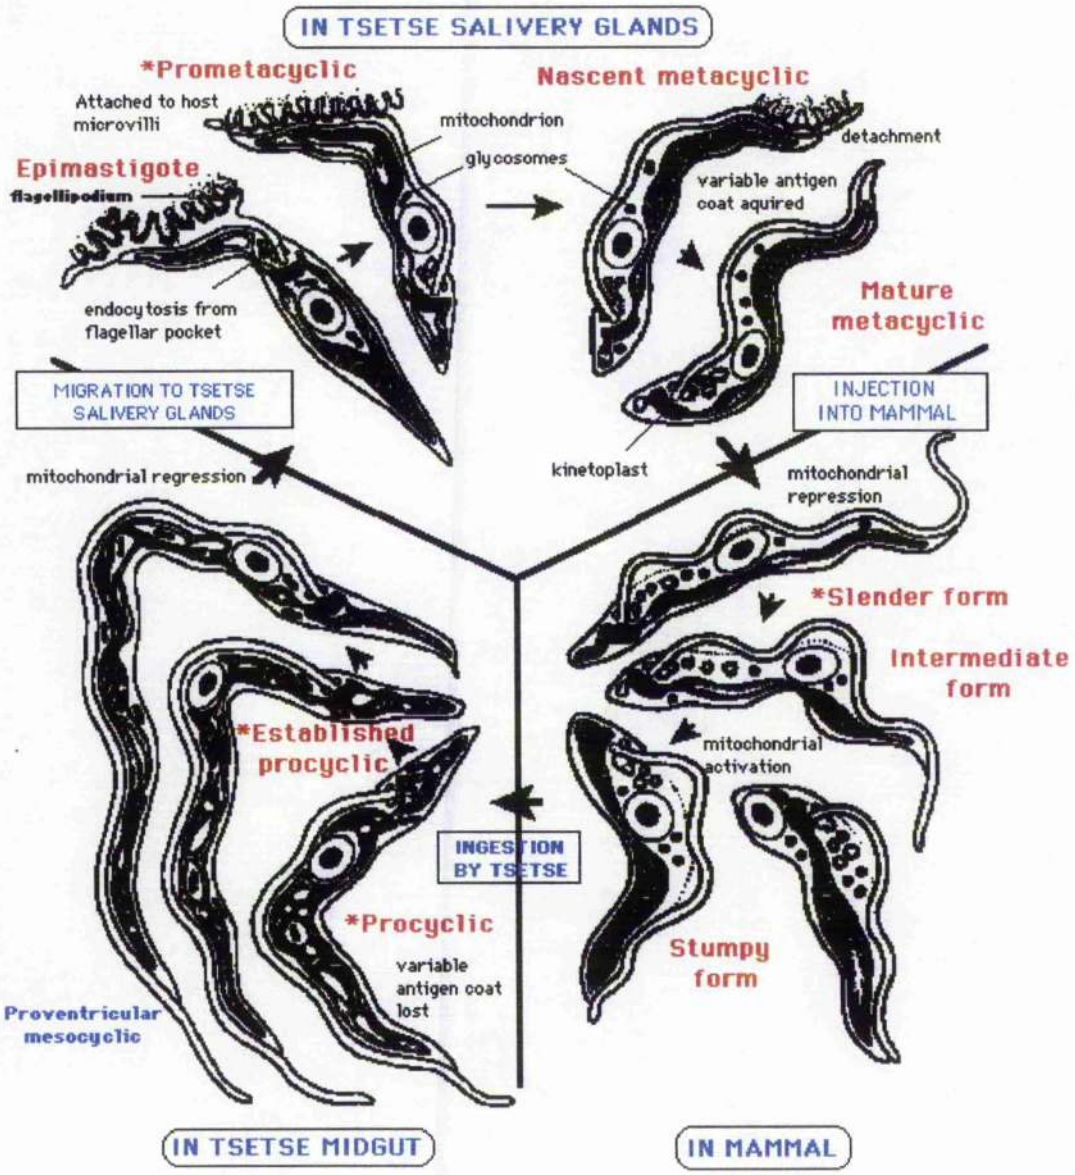

Figure 1.2: Life cycle of *Trypanosoma brucei*. Schematic representation of the developmental cycle in a mammal and in a tsetse fly vector.
Reproduced from http://www.tulane.edu/~dmsander/WWW/224/Parasitology.htm

This stage undergoes multiplication within the salivary gland, and after two to five days metacyclic (infective) forms develop from the epimastigotes (Tetley and Vickerman, 1985). With development of the metacyclic form, the parasite is now infective for the mammalian host and can be introduced into the puncture wound by the tsetse fly when it takes the next blood meal. The entire developmental cycle in the fly takes about three weeks. Once infected, the tsetse fly remains infected for life.

1.2 Control of Trypanosomiasis

1.2.1 Introduction

A concerted effort has been made to control African trypanosomiasis in both domestic livestock and humans, and there have been four main approaches taken. Firstly, avoid tsetse-infected areas, which is difficult to apply as the high risk areas are often the best grazing land. Secondly, control of the tsetse fly vector by using insecticides, fly traps and odour baits has been put to practice with varying degree of success (Schofield and Maudlin, 2001). Thirdly, the problem of animal trypanosomiasis could be overcome by increasing the use of trypanotolerant cattle that are able to resist trypanosome infection (Murray and Morrisson, 1979). Finally, the last and most widely used method for controlling both the animal and the human diseases still lies with the use of trypanocidal drugs.

1.2.2 Control of the vector

1.2.2.1 Insecticides

Following the discovery of DTT and other persistent insecticides in 1945, ground spraying became the main line of defence against tsetse flies throughout Africa for over 40 years. Selective sparying of insecticides was successfully applied to fly resting sites in riverine

fringing vegetation in Sudan in the 1950's, which led to the elimination of tsetse from 200,000 km^2 by 1978 (Snow *et al.*, 1991).

1.2.2.2 Bait technology

Bait technology involves an odour bait which attract flies to a visual target treated with insecticide. Attractants such as acetone and octenol are so effective that good control with low density of treated target (four per km^2) can be achievable (Vale *et al.*, 1988). This technique was developed further by using "live bait" such as cattle treated with insecticides. This strategy was applied with some success in Ethiopia (Leak *et al.*, 1995), Zambia (Chizyuka and Linguru, 1986) and Tanzania (Fox *et al.*, 1993).

1.2.2.3 Sterile insect technique (SIT)

Sterile insect technique involves sustained and systematic releases of sterile male insects among a wild population (Aksoy *et al.*, 2001). The insects are mass reared in large-scale insectaries where the males are sterilized by irradiation and then taken to the selected area and released by air. The sterile males fertilise wild females, which are then unable to produce progeny. Sufficient sterile males need to be released in order to achieve an over-flooding ratio sufficient to cause a decline in population size. This technique was successfully applied for the eradication of *G. austeni* from the island of Zanzibar (Shahid and Curtis, 1987).

A range of applicable techniques is available for the control of tsetse flies from simple technology such as traps, targets, treated cattle and ground spraying to more advanced technology such as aerial spraying and the release of sterile tsetse males. However, the control of tsetse flies only decrease the incidence of human and animal trypanosomiasis, and chemotherapy is still the method of choice for controlling the diseases.

1.2.3 Control of animal trypanosomiasis

Animal trypanosomiasis is an economic burden for Africa, with infection in domestic cattle causing a 20% decrease in calving, a 25% decrease in milk production and it is estimated that it causes 3 million livestock deaths per year (Seed, 2000). In addition, domestic cattle can also act as a reservoir host for *T. b. rhodesiense* (Hide, 1999). A recent HAT outbreak of *T. b. rhodesiense* in Uganda was directly associated with the import of cattle from a HAT endemic area (Fevre *et al.*, 2001). Consequently, the control of animal trypanosomiasis is important both economically and to control HAT.

1.2.3.1 Chemoprophylaxis

Animal trypanosomiasis can be prevented by the use of prophylactic drugs. The prophylactic drugs currently in use for cattle are homidium and Isometamidium. These drugs can provide protection for three months. Prophylactic drugs are particularly useful to protect animals at time of constant disease challenge. Chemoprophylaxis is an expensive, time consuming and inefficient (due to the problem of drug resistance to these drugs) solution to the problem of animal trypanosomiasis.

1.2.3.2 Chemotherapy

Treatment of animal trypanosomiasis relies on three drugs: homidium, Berenil and isometamidium chloride. Isometamedium chloride, a conjugate of ethidium and part of the Berenil molecule, is used exclusively in veterinary typanosomiasis. All three drugs are used both prophylactically and therapeutically against *T. congolense*, *T. brucei* and *T. vivax*. For all major species of trypanosomes (*T. congolense, T. vivax* and *T. evansi*) resistance to Isometamidium has been reported (Anene *et al.*, 2001). Multiple resistant population of *T. congolense* have also been described (Afewerk *et al.*, 2000). Cymelarsan, used for the treatment of trypanosomiasis in camels, has also been shown to be very effective against *T. b. brucei, T. evansi*, and *T. equiperdum* in buffalo, goats and

pigs *in vitro* (Berger and Fairlamb, 1994). Cymelarsan dissociates rapidly into Melarsen oxide, thought to be the active form of the drug (Berger and Fairlamb, 1994).

1.2.3.3 Trypanotolerant cattle

Breeds of cattle which are tolerant to trypanosomiasis occur in some part of Africa (Murray *et al.*, 1984). Although the use of trypanotolerant cattle in Africa is a way of controlling trypanosomiasis in cattle, it is not *per se* a solution to the problem, since trypanotolerant animals still suffer loss of productivity due to chronic trypanosome infection and can succumb to the disease under high challenge. In addition, these animals would still be reservoir host for the human infective trypanosomes and so will not reduce the incidence in HAT (Fevre *et al.*, 2001).

1.2.4 Control of Human African Trypanosomiasis

The process of antigenic variation has hindered efforts to develop vaccine against the parasite and so chemotherapy has remained the major means of controlling HAT (Pays, 1995). There are currently four drugs available for treating HAT: Suramin, Pentamidine, Melarsoprol, and DL-α-difluoromethylornothine (DFMO). The use of a particular drug depends on the stage of HAT being treated and relates to the ability of the drug to penetrate the blood-brain barrier. Suramin and Pentamidine treatment are restricted to the early stage of HAT while Melarsoprol and DFMO are lipophilic and thus able to cross the blood brain barrier. This characteristic makes them the drugs of choice for the treatment of the late stage of HAT when the parasite grow in the brain.

With the exception of DFMO, which was introduced for the treatment of West African HAT in 1990, all of the antitrypanosomal drugs were discovered more than 40 years ago.

1.3 Administration, uptake and mode of action of trypanocidal drugs

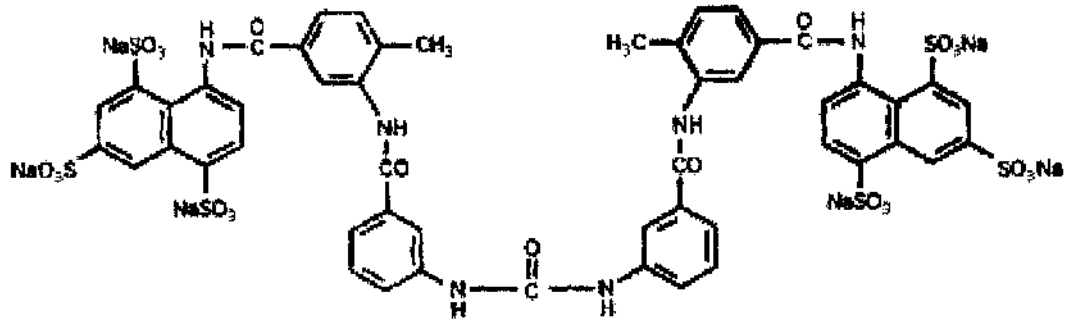
The main drugs for the treatment of the first stage of HAT are suramin and Pentamidine, which were introduced in 1922 and 1941 respectively. After the parasite has invaded the central nervous system (second stage of HAT), only two drugs are effective, namely Melarsoprol introduced in 1949 and DFMO introduced in 1990.

1.3.1 Suramin

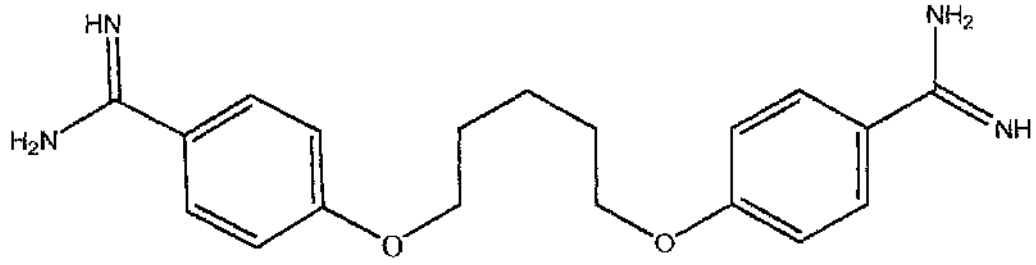
Suramin was first introduced for the treatment of early stages of HAT in 1922, and is especially effective for treating *T. b. rhodensiense* infections (Wang, 1995). It is also effective against *T. b. gambiense, T. b. brucei, T. evansi* and *T. equiperdum* (Hawking, 1963). Suramin is usually administered to patients in five intravenous injections at a dosage of 20 mg/kg body weight once every five to seven days.

The structure of Suramin is shown in Figure 1.3. It has been found to bind to albumin and low-density lipoprotein (LDL) in serum. Fairlamb & Bowman (1980) demonstrated the rapid uptake of Suramin in the presence of serum proteins in trypanosomes. The uptake was 18 fold higher than could be explained by fluid endocytosis alone, therefore suggesting a high affinity transport system. Evidence for receptor-mediated endocytosis of host LDL in both bloodstream and procyclic forms was discovered by Coppens *et al.* (1988) who proposed that Suramin was entering trypanosomes bound to LDL through LDL- receptor mediated endocytosis (Coppens *et al.*, 1988). In addition Suramin was found to inhibit LDL-binding and uptake by *T. brucei* in a concentration dependent manner, suggesting competition for the LDL-binding site on the LDL-receptor

A)



B)



C)

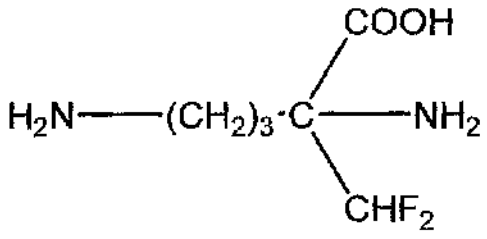


Figure 1.3: **Structure of Suramin, Pentamidine and DFMO**. Suramin (A) and Pentamidine (B) are used for treatment against early stage trypanosomiasis. DFMO (C) is in use for the treatment of late stage trypanosomiasis.

(Vansterkenburg *et al.*, 1993). However, Pal *et al.* (2002) recently demonstrated that while Suramin was transported by receptor-mediated endocytosis in *T. brucei*, the LDL-mediated endocytosis was only indirectly involved in Suramin uptake. The specific route by which Suramin enters the trypanosomes has not yet been identified.

Suramin is an inhibitor of many different dehydrogenases and kinases from mammalian, bacterial and fungal sources. In *T. brucei*, Suramin was found to inhibit dihydrofolate reductase and thymidine kinase as well as being a potent inhibitor of many of the glycolytic enzymes in *T. brucei* (hexokinase (HK), phosphoglucoisomerase (PGI), phosphofructokinase (PFK), triosephosphate isomerase (TIM), aldolase (ALDO), glyceraldehyde-3-phosphate dehydrogenase (GAPDH), phosphoglycerate kinase (PGK), glycero-3-phosphate dehydrogenase (GPDH), and glycerol kinase (GK)) (Misset and Opperdoes, 1987). It was thus proposed that Suramin acted by blocking glycolysis in trypanosomes. This theory on the mechanism of antitrypanosomal action of Suramin is contradicted by the fact that all these glycolytic enzymes are confined within single membrane bound microbody organelles, termed the glycosome. As it is unlikely that the glycosome will take up Suramin by passive diffusion or endocytosis due to its high negative charge, the nine glycolytic enzymes would be protected from Suramin via compartmentalisation. However, the genes encoding these enzymes are located in the nucleus and the enzymes are synthesised on free ribosomes in the cytoplasm with subsequent import into the glycosome within three to five minutes without any proteolytic modification. One possible mode of action of Suramin could be that the inhibition of glycosomal proteins import leading to a gradual decrease of enzyme concentration in the glycosome and a slowing down of energy metabolism (Wang, 1995).

1.3.2 Pentamidine

The aromatic diamidine Pentamidine (1,5-bis (4'-aminidinophenory) pentane; Figure 1.3) introduced in 1937 has been used for decades in the treatment of HAT, antimony-resistant leishmaniasis (Sereno *et al.*, 2000). It is effective against the early stage of *T. b. gambiense* infection and is given at a dose of 4 mg/kg body weight by 7 to 10 intramuscular injections daily or on alternative days. Pentamidine is the only drug that has been use for large scale prophylaxis (Dukes, 1984).

African trypanosomes accumulate Pentamidine to millimolar concentrations via a high affinity transport system which is energy dependent and competitively inhibited by other diamidines (Damper and Patton, 1976). The Pentamidine transporter was identified in 1995 as the P2 adenosine/adenine transporter (Carter and Fairlamb, 1993). Two more Pentamidine transporters were recently described, a high-affinity pentamidine transporter (HAPT1) and a low affinity Pentamidine transporter (LAPT1) (de Koning, 2001).

The mechanism of Pentamidine antitrypanosomal action is unknown. Pentamidine has been shown to inhibit thymidylate synthetase, an enzyme present in various trypanosomatids, (Gutteridge, 1969) as well as S- adenosyl-L-methionine decarboxylase (Bittoni *et al.*, 1986), mitochondrial topoisomerase II (Shapiro, 1993), mitochondrial membrane potential (Vercesi and Docampo, 1992), dihydrofolate reductase (Waalkes and Maluku, 1976), thymidylate synthetase (Kaplan and Myers, 1977) and calcium transport (Benaim *et al.*, 1993). Given this range of inhibitory activities, it is difficult to define a specific selective mode of action.

1.3.3 DFMO

DFMO (Figure 1.3) was primarily developed as an anti-tumour proliferation and modulation of cell differentiation drug but the clinical trials showed poor results. DFMO was first synthesised as a potential suicide inhibitor of ornithine decarboxylase (ODC). ODC is the key enzyme in the pathway leading to biosynthesis of polyamines: putrescine, spermidine, and spermine, which are essential for the proliferation of prokaryotic as well as eukaryotic cells. DFMO depletes the polyamines putrescine and spermidine from *T. brucei* both *in vitro* and *in vivo*. Subsequently, the DFMO-treated trypanosomes are transformed to a non-dividing, short, stumpy form that is apparently incapable of changing its VSG and is eventually killed by the host immune reaction (Bitonti *et al.*, 1986b). DFMO is relatively ineffective against *T. b. rhodensiense* infections. Its inefficiency in treating *T. b. rhodesiense* infections is explained by the short half-life of ODC and high expression levels of ODC in *T. b. rhodesiense* as compared to *T. b. gambiense* (Itens *et al.*, 1995; Itens *et al.*, 1997).

The uptake of DFMO in bloodstream forms of *T. b. gambiense* and *T. b. rhodesiense* is thought to be a combination of passive and mediated diffusion, depending on the extracellular concentration (Bitonti *et al.*, 1986; de Koning, 2001). DFMO can be accumulated in trypanosomes to millimolar levels (de Koning, 2001). DFMO is a remarkably safe drug but it requires to be administered intravenously at a large dose of 400 mg/kg body weight per day in four equal doses every 6 h for 14 days (Van Nieuwenhove *et al.*, 1985).

1.3.4 Arsenicals

The class of melaminophenyl arsenical drugs use for the treatment of trypanosomiasis includes Melarsoprol, Cymelarsan, Trimelarsan and Melarsen oxide (Figure 1.4). Melarsoprol is the only arsenical drug currently used for the treatment of HAT and was made available in 1949. Cymelarsan is licensed only as a veterinary drug against trypanosomiasis in camels and the other two drugs have not been licensed. Until 1990, Melarsoprol was the only drug capable of treating late stage *T. b. gambiense* and *T. b. rhodesiense* infections. It is administered intravenously at a dose of 3.6 mg/kg body weight in three to four series of four injections separated by at least one week (WHO). A major problem with Melarsoprol is its toxic side effects. The encephalopathic syndrome, which is reported to occur in 2-10% of treated cases is fatal in 50-70% of these cases, constitutes the most important complication of Melarsoprol treatment (Keiser and Burri, 2000).

In bloodstream forms of *T. brucei*, Melarsoprol is rapidly metabolized into Melarsen oxide (Keiser and Burri, 2000; Keiser *et al.*, 2000). Melarsen oxide was shown to be the active metabolite against HAT. Water soluble melaminophenyl arsenicals such as Melarsen oxide are transported into trypanosomes by the P2 adenosine/adenine transporter (Carter and Fairlamb, 1993; de Koning and Jarvis, 1999; de Koning, 2001). It is unknown whether the lipophilic Melarsoprol is also transported by the same mechanism (de Koning, 2001). In procyclic forms however, Melarsoprol crosses the membrane by passive diffusion (Scott *et al.*, 1997). A summary of transporters involved in the uptake of trypanocydal drugs discovered so far in bloodstream trypanosomes is given in Figure 1.5.

Melarsoprol leads to the rapid lysis of trypanosomes, but its mechanism of antitrypanosomal action is not well understood. It has been proposed that trivalent

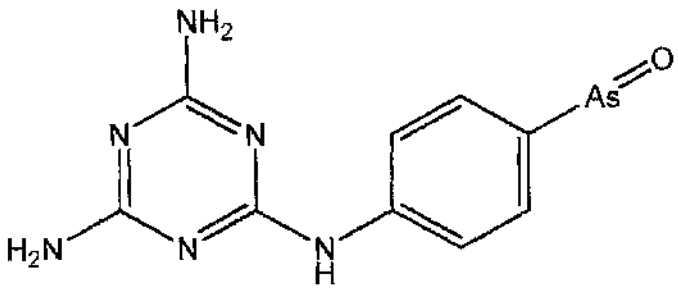

Figure 1.4: Structure of the melaminophenyl arsenical drugs. Cymelarsan (A) and Melarsoprol (B) dissociate primarily into Melarsen oxide (C).

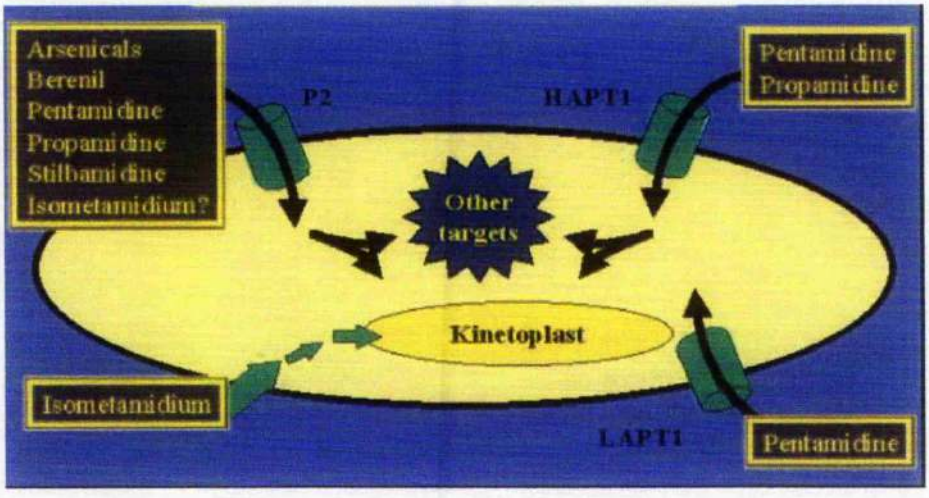

Figure 1.5: **Transport of trypanocides in bloodstream forms of *T. brucei*.** Arsenical drugs (Melarsoprol, Cymelarsan, etc.) and diamidines share a common transporter: the P2 transporter. Reproduced from de Koning (2001).

arsenicals with two replaceable ligands have a high affinity for intracellular thiols such as trypanothione and dihydropoamide plus several enzymes including trypanothione reductase (Fairlamb *et al.*, 1989), 6-phosphogluconate dehydrogenase (Hanau *et al.*, 1996) and glycerol-3 phosphate dehydrogenase (Denise *et al.*, 1999). However, these inhibitory effects have not been directly linked to cell lysis. *In vivo*, Melarsoprol is quickly metabolised into Melarsen oxide, which was shown to be an active metabolite (Keiser *et al.*, 2000). Melarsen oxide was first believed to act by blocking glycolysis in trypanosomes through inhibition of the pyruvate kinase. However, later studies indicated that the lytic effect of Melarsen oxide is not the primary result of inhibiting pyruvate kinase (Cunningham *et al.*, 1994). Thus, while a number of enzyme activities have been shown to be inhibited by the arsenicals, the nature of the primary target of these inhibitors is still unclear. Whether the basis for their selective action is due to their rapid and specific uptake by the P2 transporter followed by inhibition of a range of enzyme activities or is via some other mechanisms still need to be investigated. The rate of entry of the drug into the CSF is related to the lipid solubility of the unionised molecule. Melarsen oxide and Melarsoprol have high lipid solubility. At physiological pH of 7.4, only 0.2% of Melarsoprol is unionised, indicating that only a small amount of the drug is available to cross the lipid membrane.

1.4 Arsenical resistance in T. brucei

1.4.1 Definition of drug resistance

Treatment failures with Melarsoprol were reported as early as 1986 (WHO). However, the rates of treatment failure remained at low and constant levels of 1 to 10% (WHO, 1986; Pepin and Milord, 1994). This situation has changed in recent years with reports of much higher rates of treatment failure from northern Uganda and northern Angola. Up to 25% of

treated patients in Angola and 30% in Uganda were reportedly non-responsive to Melarsoprol therapy (Legros *et al.*, 1999, Matovu *et al.*, 2001). Treatment failure can be defined as the "absence or insufficient effect of drug action after administration of a normally effective dose". It is usually observed as the presence of trypanosomes in a sample from patients within one month of treatment completion or a complete lack of clinical response during the course of treatment. Drug resistance, however, was defined in 1963 by the WHO as the "ability of a parasite strain to multiply or survive in the presence of concentrations of a drug that normally destroy parasites of the same species or prevent their multiplication. Such resistance may be relative (yielding to increased doses of the drug tolerated by the host) or complete (withstanding maximum doses tolerated by the host)".

The difference between the two is fundamental as although it is true that drug-resistance will bring about drug failure, it is not necessarily true that drug failure is the result of drug resistance since resistance is only one of many factors affecting drug failure (Borst and Ouellette, 1995).

1.4.2 Biochemical and molecular basis of arsenical resistance in *T. brucei*

Cross-resistance between the diamidines such as Pentamidine and the melaminophenyl arsenicals has been reported in laboratory-induced drug resistant strains of *T. brucei* (Fairlamb *et al.*, 1992). Cross-resistance between two different classes of drugs generally implies an alteration in either a common uptake/efflux mechanism or a common target (or both).

Carter and Fairlamb were the first to demonstrate the transport of Melarsen oxide via an adenosine transporter, later referred to as P2 transporter, into bloodstream forms of trypanosomes (Carter and Fairlamb, 1993). This provided the first basis for the search for the molecular mechanism of arsenical resistance in *T. brucei*. Since this first report, studies of arsenical resistance in *T. brucei* have mainly centred on this transporter. The gene encoding the transporter, *TbAT1,* was cloned in 1999 and a structure for the protein was proposed from the sequence (Mäser *et al.*, 1999). Sequencing of *TbAT1* from a laboratory-derived arsenical resistant line of *T. brucei* demonstrated the presence of ten point mutations in the gene, six of which conferred an amino acid substitutions in the protein sequence (Mäser *et al.,* 1999). In addition, cloning of the *TbAT1* gene in yeast also supported the involvement of the P2 transporter in resistance to Melarsoprol. The strain of *Saccharomyces cerevisiae* used had no transporter for exogenous adenosine and was unable to use it as a purine source. These cells defective in purine biogenesis were transformed with *TbAT1* gene and grown on agar containing adenosine as sole purine source. The transformed yeasts were able to grow on adenosine as sole source of purine. In addition, expression of the *TbAT1* gene in yeast rendered the yeast sensitive to Melarsoprol. However, the expression of the mutated *TbAT1* gene in yeast did not confer sensitivity to Melarsoprol, demonstrating that the mutated gene was not able to mediate the transport of the drug in the cell (Mäser *et al.*, 1999).

Analysis of the P2 transporter by competitive uptake with adenosine revealed that the P2 transporter also mediates the transport of Berenil, Pentamidine, Propamidine and Stilbamine in addition to the arsenicals (Figure 1.5) (de Koning, 2001), explaining the cross-resistance observed between the diamidines and melaminophenyl arsenical drugs (Fairlamb *et al.*, 1992; Frommel and Balber, 1987). The P2 transporter was shown to be

selective for adenine and adenosine with little affinity for other purines, but it also mediated the transport of diverse structures such as Melarsoprol and Pentamidine (Carter *et al.*, 1995; de Koning and Jarvis, 1999). The paradox of the selectivity of the P2 transporter was resolved with the determination of its substrate recognition motif. The substrate recognition motif of the P2 transporter was determined by assessing the inhibition of adenosine transport by a series of adenosine analogs (Figure 1.6) (de Koning and Jarvis, 1999; de Koning, 2001). However, preliminary analysis of the P2 transporter in Melarsoprol resistant *T. b. rhodesiense* isolated from relapsed patients revealed that only 50% of the isolates contained the mutated transporter (Matovu *et al.*, 2001). In addition, a knockout of *TbAT1* in *T. brucei* conferred only a three fold resistance to Melarsoprol, which is well below the level of resistance obtained in laboratory-induced lines (Matovu *et al.*, 2003). In addition, two laboratory-induced Cymelarsan resistant lines (247 and 386) exhibited the resistance phenotype in procyclic stages (Scott *et al.*, 1996) for which P2 transporter activity cannot be detected (Figure 1.7) (de Koning *et al.*, 2000). Consequently the resistance to Melarsoprol exhibited by these lines cannot be accounted for by mutations in the P2 transporter.

The observation that a considerable proportion of wild type *TbAT1* were found among relapsed patients, that only three fold resistance to Melarsoprol was observed in the *TbAT1* knockout line and that procyclic forms can exhibit arsenical resistance strongly indicate that *TbAT1* is not the only gene responsible for conferring arsenical resistance in *T. brucei*. A model whereby the loss of a single transporter could mediate cross-resistance to all diamidines and melaminophenyl arsenical drugs and high level arsenical resistance appears, in view of these findings, incomplete.

1.5 The study of mechanisms of drug resistance

From the preceding discussion it is clear that the field of drug resistance is far from fully understandood or defining the genes that determine drug resistance in trypanosomes and therefore explaining the mechanisms by which resistance occurs. In trypanosomes there are a range of techniques that could be applied to investigate the mechanisms of resistance and these are reviewed below.

1.5.1 Genetic tools

1.5.1.1 Classical genetic analysis

While *T. brucei* multiplies mainly by binary fission, a mating system exists and genetic exchange was clearly demonstrated by laboratory co-transmission studies (Sternberg and Tait, 1990). There is evidence for segregation of alleles and recombination between loci (Turner *et al.,* 1990). However, it appears that genetic exchange is non-obligatory and the frequency at which it occurs in natural population is still unknown (Sternberg *et al.*, 1989). The genetic basis of a phenotype can be determined by the analysis of the progeny from a cross of parental stocks with different phenotype (drug sensitive/ resistant stocks). To determine the region of the genome in which gene or genes associated with the particular phenotype is located, a genetic map must have been previously established. This genetic map, made using molecular markers, enables linkage analysis to be performed. The co-segregation of markers on the genetic map with the phenotype of the progeny of the cross determine the location, between two markers, of the gene or genes of interest. The efficiency of the linkage analysis depends on the resolution of the genetic map. In general linkage can be established within several hundred kilobases, which might contain several genes. Analysis using RNAi or gene knockout is then required to identify the specific gene.

Genetic maps for chromosome I and II of *T. brucei* are available (Hall *et al.*, 2003; El Sayed *et al*, 2003). A recent study has demonstrated the existence of crossing over and the size of the recombination unit was calculated which suggested that at least one crossover will occur per chromosome at meiosis (Tait *et al.*, 2002). Crosses between naturally occurring variation in drug resistance between parental stocks of 386/247, 386/927 and 247/927 were produced (Hope *et al.*, 1999). The linkage analysis of the drug resistance phenotype in the progeny from the cross between 247/927 determined the location of a single gene conferring resistance between two closely located markers on chromosome II (Dr S. Taylor, personal communication).

The main limiting factor in the study of inheritance patterns of traits is the available phenotypic variation between parasite stocks. In addition, there are difficulties in obtaining and cloning large number of hybrid progeny, which determine statistical significance of segregation phenotypes.

1.5.1.2 Reverse genetic analysis

Two powerful reverse genetic techniques are available for the analysis of gene function in *T. brucei*. Firstly the use of gene knockouts based on homologuous recombination and secondly RNA interference (RNAi) which allows the knockdown of specific transcripts. These techniques are largely used when a specific gene is being studied and can be used to define whether the gene is essential or the loss leads to a specific phenotype. RNAi is currently being used on a large scale basis to knockdown every identified gene on chromosome I. These technique are particularly useful for confirming that an identified gene has a particular function.

RNAi is the process by which gene-specific double stranded RNA (dsRNA) elicits degradation of mRNA. This phenomenon occurs post-transcriptionally, which makes it the strategy of choice to down-regulate the expression of repeated genes. The first observation of degradation of mRNA by gene-specific dsRNA in *T. brucei* was made in 1998 (Ngô *et al.*, 1998). RNAi technology has become the method of choice to down-regulate gene expression in a variety of organisms. RNAi is particularly well suited for diploid organisms such as trypanosomes as transcripts from both alleles are down regulated. Placement of integrated RNAi constructs under control of the *tet* repressor system or the T7 promoter system provide a powerful method to probe gene function in trypanosomes. RNAi technology has been applied in *T. brucei* to study the function of gamma-glutamylcysteine synthetase (Huynh *et al.*, 2003), surface protease GP63 (LaCount *et al.*, 2003), gamma tubulin (McKean *et al.*, 2003) and farnesyl phosphate synthase (Montalvetti *et al.*, 2003). The RNAi technique is simple and efficient, but the induction of mRNA degradation by RNAi failed to provide a phenotype in 50% of the cases (Ullu *et al.*, 2002). In addition, RNAi technology requires the pre-selection of genes whose function are of interest. In the case of the mechanism of Cymelarsan resistance in trypanosomes the selection of genes is not obvious as the drug targets and the mode of action of the drug are still unknown.

1.5.2 Micro-array expression analysis

One approach to identifying the mechanisms of drug resistance is by comparative analysis of gene expression between drug sensitive and resistant isolates. One of the hypothesis assumed in employing this technique is that a change in gene expression causes resistance.

Micro-array expression analysis is based on the construction of ultra-high density DNA micro-arrays on glass microscope slides followed by hybridisation with fluorescently labelled cDNA and analysis using a con-focal laser scanner. The advantages of this technique are two-fold. Firstly, the micro-arrays allow the simultaneous interrogation of thousands of cDNA clones or oligonucleotides with mRNA from various resistant lines of parasites at once. Secondly, the use of fluorescently labelled probes and con-focal laser microscopy allows partial quantitative determination of the relative expression levels of many genes in a single experiment by comparing different resistant lines (Celis *et al.*, 2000). A large amount of data are generated by this approach and the analysis of the data can be complex. Reproducibility can be quite low and so for statistical analysis micro-arrays studies requires the experiment to be repeated several times. In addition, micro-arrays study the expression of mRNA level in an organism. One mRNA molecule can give rise to anything from one to a few dozen gene-products in higher eukaryotes depending upon the degree of post-translational modification, cleavage events and the degree of differential exon splicing possible within exon-rich genes. Micro-array technology has been applied to the study of stage specific gene expression in *T. brucei* (Diehl *et al.*, 2002) and *T. cruzi* (Minning *et al.*, 2003).

1.5.3 Proteomic techniques

1.5.3.1 Definition

The term "proteome" first appeared in literature in July 1995 and refers to the "total protein complement of a genome". Wasinger *et al.* (1995) qualified this further by stating that "although 'proteome' refers to the total complement able to be encoded by a given genome, it is unlikely that: 1- the totality of this potential for protein expression will be realised at any given instant, and 2- the detection threshold of 2 dimensional gel electrophoresis (2DE) for low copy number molecules will enable all translated proteins to

be visualised. Proteome analysis must depend upon experimental design and the need to examine several physiological states both *in vitro* and *in vivo*."

In general, the proteome represents the protein pattern of an organism, a cell, an organelle, or even a body fluid determined quantitatively at a certain moment and under precisely defined conditions. Furthermore, the proteome reflects the current metabolic status of the corresponding cell (or organism) which is determined by manifold interactions of the different molecules that are currently still difficult to analyse and by a range of environmental parameters. Unlike the genome, the proteome is thus a highly dynamic system which is characteristically altered by changes in environmental conditions. Analysis of the total protein complement of a genome has only recently become possible due to improvements in the reproducibility of separation technologies in association with immobilised pH gradients, the availability of computer software for the construction of polypeptide maps and the comparison of gel separations by advanced image analysis and the sensitivity and applicability of mass spectrometry to the analysis of proteins separated by two dimensional gel electrophoresis (2DE).

1.5.3.2 Applicability of proteomics study to trypanosomes

Analysis of the complete sequences from chromosome I and II of *T. brucei* provides some information about the structure and gene content of the chromosomes. Both chromosomes have a gene-rich core, a region containing a retro-transposon hotspot, VSGs adjacent to telomeres and may carry a bloodstream expression site with upstream 50 bp repeats (El-Sayed *et al.*, 2003, Hall *et al.*, 2003). Analysis of these two chromosomes revealed long arrays of genes located on the same coding strand, each array separated by a strand switch region. This arrangement of the genes along the chromosomes is consistent with polycistronic transcription of trypanosome genes (Tschudi and Ullu, 1988), whereby long

mRNA transcripts of multiple genes are processed to individual mRNAs by trans-splicing of a 5' spliced leader and addition of a poly-A tail (Matthews *et al.*, 1994). Analysis of the strand switch regions revealed a lack of common sequence motifs that could represent specific promoters capable of controlling gene transcription during the development of *T. brucei*. Only two promoters have been identified so far in the *T. brucei* genome. One controls the transcription of the VSG genes (Zomerdijk *et al.*, 1990) the other one controls the transcription of the procyclin gene (Sherman *et al.*, 1991). With such a gene organisation, any control at the level of transcription initiation would imply that all genes belonging to the same unit are regulated in the same way. This does not appear to be the case. Instead, control of gene expression in *T. brucei* is most likely accomplished at the post-transcriptional level, by both regulating the levels of mRNA and the levels and activities of the expressed proteins (post-translational modifications). This view is supported by the study of the regulation of cytochrome c protein in *T. brucei* (Torri *et al*, 1993). The bloodstream trypanosomes synthesise apocytochrome c protein at levels comparable to that of procyclic trypanosomes, but protein turnover prevents accumulation of cytochrome c protein in the bloodstream form. A similar observation applies to cytochrome c reductase.

The importance of protein-based analysis is its ability to study post-transcriptional control as well as post-translational modifications such as phosphorylation, glycosylation, acylation and methylation. Proteins determine the biological phenotype of an organism and proteins are the primary targets for most therapeutic agents. The advantages of proteomic studies are that they give a global picture of the changes taking place, whereas previous drug resistance studies have concentrated on individual enzymes or proteins and not on total response (Barett *et al.*, 2000). Techniques such as 2DE, quantitative computer image

analysis and protein identification can be use to create a "reference map" of all detectable proteins. Such reference maps establish patterns of normal gene expression in the organism and allow the examination of some post-translational protein modifications which are functionally important for many proteins. In addition, comparative maps can be established by analyzing variants of the wild type and so identify differences associated with a mutant or a different physiological condition. It is possible to screen proteins systematically from reference maps to establish their identities (Wilkins *et al.*, 1996).

Very few proteomic studies have been performed on trypanosomes. Three proteomic studies were performed in the 1980s on *T. brucei* using carrier ampholytes for isoelectric focussing in the first dimension. These were used to detect difference in VSG expression between cloned populations (Pearson *et al.*, 1981) or to detect differences in protein expression between subspecies (Anderson *et al.*, 1985; Pearson and Jenni, 1989). The use of carrier ampholytes meant that the reproducibility of the gels was difficult. In addition, no easy/fast methods were available to identify the differentially expressed proteins. The availability of *T. brucei* genome sequences and of new technologies, for isoelectric focussing and identification of protein separated by 2DE using mass spectrometry methods, have removed most of the limitations of the proteomic studies. Recently, a protocol was developed for the extraction and separation of proteins from *T. brucei* using IPG technology (van Deursen *et al.*, 2003). It is expected that the new technologies will spark an increase in research activity concerned with the analysis of the *T. brucei* proteome.

1.6. Aim

The aim of this project is to use proteomics to understand the mechanisms of arsenical drug resistance in *T. brucei* parasites. This is a particularly important area, given that there are only four drugs available for the treatment of HAT. Further, resistance to Melarsoprol treatment, the drug of first choice for late stage trypanosomiasis, has been reported in many parts of Africa. One mechanism by which drug resistance to Melarsoprol can be generated has been described and involves the alteration of the adenosine P2 transporter. However, there is preliminary evidence suggesting that other mechanisms are very likely to be involved.

Isogenic lines of parasites that are sensitive or resistant to Cymelarsan (a close analogue of Melarsoprol) have been described previously (Scott *et al.*, 1996, 1997). Comparison of the proteins expressed by each of these lines can be made by 2DE in order to identify specific polypeptide alterations associated with the resistant phenotype. The identity of the proteins showing differences can then be determined using mass spectrometry followed by the screening of gene sequence databases.

The specific objectives of the project are:

- To find the best solubilisation method for proteins from trypanosomes to maximise sensitivity and reliability of proteomic analysis
- To construct a partial proteome map of *T. brucei*
- To identify changes in the polypeptide profile of *T. brucei* that are associated with arsenical resistance
- To characterise the polyptetides associated with Cymelarsan resistance

- To conduct downstream analyses of any proteins identified associated with drug resistance, with the aim of developing testable hypothesis of the mechanism of arsenical resistance in *T. brucei*

Chapter II

The development of proteomic techniques for *T. brucei*

2.1 Introduction

Two-dimensional gel electrophoresis (2DE) has come into widespread use since the publication, in the early seventies, of methods combining isoelectric focussing (IEF) in the first dimension with sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) in the second dimension (Ames and Nikaido, 1976). In recent years, the technique of 2DE was improved by the introduction of immobilised pH gradients (IPG) for the separation of proteins by IEF to replace the use of carrier ampholytes. Immobilised pH gradient gels are made by a small number of defined chemicals (acrylamido buffers) which are covalently linked to a polyacrylamide matrix. These allow true steady-state focussing, which greatly increases the reproducibility of the technique.

The protocol for 2DE using immobilised pH gradients is well developed and has recently been reviewed (Görg *et al*, 2000). However, sample preparation, i.e. the extraction and solubilisation of proteins in a solution compatible with 2DE, still requires to be determined empirically for each organism or cell fraction under study. For efficient protein solubilisation and high resolution on 2D gels it is necessary to achieve complete disruption of molecular interactions, to obtain single polypeptides, and maintain this state throughout the separation process. Many protocols have been developed to achieve this aim. Table 2.1 illustrates the evolution of sample preparation methods for proteins from protozoan parasites by 2DE. It is now generally accepted that a combination of chaotropes (i.e. urea and thiourea) and zwitterionic amphiphilic compounds (e.g. CHAPS or SB3-10)

Sample	IEF method	Solubilisation method	Detection	Reference
T. brucei	CA-IEF	0.25% NP-40, 2 mM PMSF	Iodinated lectins	Pearson *et al.*, 1981
L. tropica	CA-IEF	0.5% Triton X100, 20 mM EDTA, 2 mM PMSF, 10 mM Iodoacetamide	^{125}I labelling	Handman *et al.*, 1983
T. brucei	CA-IEF	9 M urea, 5% 2-mercaptoethanol, 4% Nonidet P-40, 2% ampholites	^{35}S labelling	Anderson *et al.*, 1985
T. brucei	CA-IEF	9 M urea, 2% 2-mercaptoethanol, 4% Nonidet P-40, 2% ampholites	^{35}S labelling	Pearson and Jenni, 1989
T. gondii	CA-IEF	9.8 M urea, 0.3% SDS, 3% NP 40, 2% ampholites	^{3}H labelling	Achbarou *et al.*, 1991
T. gondii	IPG-IEF	7 M urea, 2 M thiourea, 4% CHAPS, 1% DTT, 2% IPG buffer, 0.05% Triton X-100	Coomassie blue staining	Dlugonska *et al.*, 2001; Nischik *et al.*, 2001,
T. gondii	IPG-IEF	8 M urea, 2% CHAPS, 22 mM DTT, 0.5% IPG buffer,	Silver and Coomassie blue staining	Cohen *et al.*, 2002
L. infantum	IPG-IEF	7 M urea, 2 M thiourea, 4% CHAPS, 40 mM Tris base, 1 mM PMSF	Silver staining	El Fakhry *et al.*, 2002
T. brucei	IPG-IEF	9 M urea, 2 M thiourea, 2% CHAPS, 65 mM DTT, 0.5% IPG buffer, cocktail of protease inhibitors	Silver staining	Van Deursen *et al.*, 2003

Table 2.1: Development of solubilisation methodology for 2DE analysis of parasitic proteins. Selected examples from the literature to illustrate the evolution of solubilisation methodology and 2DE analysis. The use of IPG-IEF was a significant milestone in the analysis of parasitic proteins by 2DE.

in the extraction buffer are essential to solubilise most proteins from a wide range of organisms (Rabilloud *et al.*, 1997, Rabilloud, 1998).

The limitations of 2DE separation are well documented and is particularly evident for membrane proteins (Santoni *et al.*, 2000a; Santoni *et al.*, 2000b). The major obstacle of global 2DE separation remains the solubilisation of all the proteins from a sample with one sample preparation method. There are three reasons for this obstacle: first, many hydrophobic proteins are not solubilised in the non-detergent isoelectric focusing sample buffer (Santoni *et al.*, 2000b), second, solubilised proteins are prone to precipitation at their isoelectric point (Adessi *et al*, 1997) and third, hydrophobic proteins transfer inefficiently to the second dimensional gel (Wilkins *et al.*, 1998). The limited dynamic range of protein visualisation is also an issue because membrane proteins are typically lower in abundance compared with most soluble proteins. In addition, membrane proteins are heterogeneous due to the differential glycosylation of extracellular domains, and this results in membrane proteins focusing over a wide pH range during IEF, producing streaks on the 2D gels.

Sample preparation is the first important step of every proteome analysis. In this chapter, a comparison of three protocols for the extraction and solubilisation of proteins from *T. brucei* was made. The protocols were based on a recently published protocol for protein extraction from *T. brucei* (van Deursen *et al.*, 2003), which uses a combination of chaotropes, zwitterionic amphiphilic compounds as well as a cocktail of protease inhibitors. Protein extracts were separated on 2D gels and compared using three criteria: the resolution of the protein spots, the number of protein spots extracted and separated which could be visualised and the distribution of the protein spots at low/high molecular

weight/pI. The reproducibility of the extraction protocol and the solubilisation of membrane proteins using the selected protocol were also assessed.

2.2 Materials and Methods

2.2.1 Commonly used reagents

All equipment and reagents for IEF and SDS electrophoresis (IPGphor, Multiphor II horizontal electrophoresis unit, Hoefer Dalt multiple vertical electrophoresis unit, EPS 3500 XL power supply, Multitemp II thermostatic circular, ImageMaster 2Delite V3.01 software, Typhoon scanner 9400, Labscan, Immobiline DryStrip, IPG buffers, TEMED, CHAPS, DTT, APS, urea, glycine, Tris, ECL kit, Hybond-C nitrocellulose membrane and Protein Silver Staining Kit) were purchased from Amersham Biosciences. TPCK, TLCK, EDTA, EGTA, Leupeptin, Pepstatin A, Coomassie Brilliant blue G250 and Gentamycin were purchased from Sigma. SDM 79 culture medium and foetal calf serum were purchased from GibcoBRL. The Sypro ruby stain and 30% polyacrylamide solutions were purchased from BioRad.

2.2.2 *In vitro* culture of procyclic trypanosomes

For this study, two laboratory stocks of *T. brucei* (TREU 927 line and STIB 386 line) were used. The lines will be referred to as 927 and 386. The lines were grown in mice from a cryopreserved stabilate before being transformed into procyclic forms by transfer of parasites to Semi Defined Medium 79 (SDM79) with 3 M cis-asconitate (Brun and Schonenberger, 1981).

Procyclic trypanosomes were grown in suspension culture either in T-25 or T-75 culture flasks (Falcon, UK). The culture medium was SDM79 supplemented with 10% heat

inactivated (56°C, 30 min) foetal calf serum and 0.2 mg Gentamycin, referred to as complete SDM79 (Brun and Schonenberger, 1979). Flasks were incubated at 25°C. Trypanosomes from 5 ml of procyclic culture at $5x10^6$ trypanosomes/ml were concentrated by centrifuging at 12,000 g for 3 min. Stabilates were made by re-suspending the trypanosomes in 0.5 ml of complete SDM79 medium and 0.5 ml of freezing medium (10% glycerol in heat inactivated foetal calf serum). The trypanosomes were then transferred into freezing vials and cooled in a cotton wool lined polyester container at -70°C for 6 h prior to transfer to liquid nitrogen.

2.2.3 SDS-PAGE mini gels

SDS-PAGE mini gels were used to assess the quality and quantity of proteins extracted using the solubilisation protocols. These were also used as the second dimension for 2DE analysis with 7 cm IPG strips.

Polyacrylamide gels (12%) were made in 0.375 M Tris-HCl pH 8.8, 1% (w/v) SDS, 1% (w/v) ammonium persulfate, 5 µl TEMED, using a 30% polyacrylamide mix.

For the quantification of protein extracts, a stacking gel was added onto the 12% gel. The stacking gel consisted of a 4% polyacrylamide gel in 0.125 M Tris-HCl, pH 6.8.

The samples were prepared as follows: 10 µl of the protein extract was mixed with 10 µl of SDS loading buffer (62.5 mM Tris-HCl, pH 6.8, 10% glycerol, 2% (w/v) SDS, 0.4 ml 2-mercaptoethanol, 0.05% (w/v) bromophenol blue), boiled for 1 min and then chilled on ice prior to loading onto the SDS-PAGE gel. Separation was performed by electrophoresis at 110 V for 2 h. Gels stained with Coomassie Brilliant blue were incubated in a Coomassie staining solution (0.5 g Coomassie Brilliant blue G 250, 100 ml acetic acid, 125 ml iso-propanol and ddH_2O up to 1 L) overnight. Gels were destained by multiple washes in a solution of 10% acetic acid/ 20% methanol until background staining had disappeared. Gel images were acquired using an AmershamPharmacia Biotech Labscan. Images of the gels

were acquired at 300 dots per inch using Labscan sv3.0 software on an Umax flatbed scanner with integrated transparency adapter.

2.2.4 Sample preparation for 2DE

A published protocol (P1, van Deursen *et al.*, 2003) for the extraction and solubilisation of proteins from *T. brucei* was compared with two modified protocols (P2 and P3). Procyclic form trypanosomes ($1x10^8$ trypanosomes/ml) were concentrated by centrifuging for 8 min at 12,000 g in a centrifuge tube and the pellet was transferred into an Eppendorf tube. The pellet was washed twice in 500 µl of phosphate buffered saline with 1% glucose (PSG), pH 7.4. Trypanosomes were resuspended and lysed in 350 µl of lysis/rehydration buffer consisting of 9 M urea, 2 M thiourea, 2% CHAPS, 65 mM DTT, 0.5% IPG buffer and a trace of bromophenol blue. 35 µl of protease inhibitor cocktail 1 (1 mM EDTA, 1 mM EGTA, 1 µg/ml Pepstatin A, 10 µg/ml Leupeptin, 100 µg/ml TPCK, 50 µg/ml TLCK) was added to the trypanosomes suspension. The trypanosomes were then incubated for 1 h at room temperature with the tubes being vortexed every 10 min, and the resulting lysate was stored at -20°C (protocol P1) (van Deursen *et al*, 2003). In the first variant of this protocol, a nuclease mixture (2,000 units/ml DNAase 1,750 units/ml RNAase A, 50 mM $MgCl_2$, 0.5 M Tris pH 8.0) was added to the sample at the same time as the lysis/rehydration buffer. The tubes were incubated on ice for 10 min before the addition of the protease inhibitor cocktail 1 and then incubated for 1 h at room temperature with vortexing every 10 min (protocol P2). In the second variant, a commercially available protease inhibitor cocktail ("COMPLETE" protease inhibitor cocktail Tablets (Roche) complemented with 10 µl of a EDTA, EGTA and PMSF solution) was used (protocol P3) instead of cocktail 1. This cocktail was added immediately to the lysis/rehydration buffer. No nucleases mixture was used in this protocol. The tubes were incubated 1 h at room temperature as described for

	Protocol P1	Protocol P2	Protocol P3
Lysis/rehydration buffer	350 µl	350 µl	350 µl
Nucleases mixture		10 µl	
Proteinase inhibitor cocktail 1	35 µl	35 µl	
Proteinase inhibitor cocktail 2			35 µl

Table 2.2: Summary of protocol P1, P2 and P3. The volumes given in the table correspond to the volumes of reagents used for the extraction of proteins from $1x10^8$ trypanosomes to be loaded onto a 18 cm 2D gels.

the other protocols. A summary of the three protocols is given in Table 2.2. The lysates were centrifuged for 5 min at 12,000 g to remove insoluble material and stored at -20°C.

2.2.5 Two-dimensional gel electrophoresis

Extracts were run in the first dimension using IPG strips rehydrated with the supernatant of proteins extracted in lysis/rehydration buffer. The volume of the protein extract used for the rehydration of the strip depended on the size of the IPG strip: 125 µl was used on 7 cm IPG strips and 350 µl was used on 18 cm IPG strips. Rehydratation and IEF were carried out on an IPGphore at 20°C and using 50 µA/strip. Rehydratation was performed at 30 V for 15 h, followed by IEF at 500 V for 500 V/h, 1,000 V for 1,000 V/h, 8,000 V for 3,975 V/h by gradient and a final stage at 8,000 V/h for 4 h (7 cm gels) or 6 h (18 cm gels).

For the separation in the second dimension, the rehydrated IPG strip was first equilibrated for 15 min by rocking in a solution of 50 mM Tris-HCl pH 8.8, 6 M urea, 30% glycerol, 2% SDS and 100 mg of DTT to reduce the proteins, and then for 15 min in a solution of 50 mM Tris-HCl pH 8.8, 6M urea, 30% glycerol, 2% SDS and 250 mg of α-Iodoacetamide (Calbiochem) in order to alkalynate the cysteine residues. The IPG strip was then rinsed in electrophoresis buffer before being embedded on a 12% SDS-PAGE gel with 0.5% (w/v) agarose. Electrophoresis buffer consisted of 25 mM Tris base, 192 mM glycine and 0.1% SDS. Gels were run at 110 V for 2 h (7 cm gels) or 110 V for 24 h (18 cm gels) at 15°C.

2.2.6 2D gel staining and image acquisition

The gels were stained either in Coomassie Brilliant blue, silver or Sypro ruby (BioRad). Staining with Coomassie Brilliant blue was performed as described for SDS-PAGE gels. Silver staining was performed using the Protein Silver Staining Kit and the automatic gel stainers according to the manufacturer's instructions. Sypro ruby staining of 2D gels was

performed following the manufacturer's (BioRad) instructions. The gels stained with Coomassie Brilliant blue or silver were imaged as described previously for SDS-PAGE mini gels. Images from gels stained with the fluorescent dye, Sypro ruby, were acquired using a Typhon scanner 9400 (variable mode imager) under the following settings: emission filter set at 560 LP green/purple, PMT= 550, laser = green 532, sensitivity normal, pixel size = 100 microns (Görg *et al.*, 2000).

2.2.7 Western blotting

Following SDS-PAGE analysis, separated proteins were transferred to Hybond-C nitrocellulose membrane by electroblotting in transfer buffer (20 mM Tris, 225 mM Glycine) using a BioRad mini transblot cell, according to the manufacturer's instructions. Proteins were transferred at 110 V for 1 h 30 min. The membrane was stained with Ponceau S to allow rapid assessment of protein transfer to the nitrocellulose membrane. The nitrocellulose membrane was then placed in blocking solution consisting of 5% skimmed milk in TBS-Tween (0.02 M Tris, 0.137 M NaCl pH 7.6, 0.05% Tween 20) and incubated overnight at 4°C. The nitrocellulose membrane was washed for 10 min in TBS-Tween at room temperature three times and then incubated for 1 h 30 min in the primary antibody diluted in TBS-Tween. Two primary antibodies raised against *T. brucei* Rab2 and Rab11 proteins were used (gift from Dr M. Field, Imperial College London). The membrane was washed for 10 min in TBS-Tween three times to remove any unbound antibody, secondary antibody, horseradish peroxidase-conjugated anti-rabbit IgG (Diagnostics Scotland, 1:1,000 dilution) in TBS-Tween, was added and incubated for 1 h 30 min at room temperature. The membrane was washed for 10 min in TBS-Tween three times. The bound conjugated antibody was detected using an ECL kit and incubation for 1 min. The surplus solution was drained from the membrane which was then exposed to the autoradiographic films from 1 to 10 min as required (Kaufmann *et al.*, 2001).

Autoradiographs were developed using a film processor (X-Ograph imaging system compact X4) according to the manufacturer's instructions.

2.3 Results

2.3.1 Assessment of the three sample preparation protocols

The three sample preparation protocols developed for the extraction and solubilisation of proteins from *T. brucei* were compared using $1x10^8$ procyclic forms trypanosomes of stock 927. The concentration of protein extracted using each protocol could not be assessed with either a Bradford technique (e.g. Coomassie Plus Protein Assay from Pierce) or an assay based on the biuret reaction (e.g. BCA Protein Assay from Pierce) because of the presence of high concentrations of urea, thiourea and DTT reagents in the lysis/rehydration buffer (data not shown). Instead, 12% SDS-PAGE mini gels were run to assess the relative concentration and quality of protein extracted (Figure 2.1). Limited differences were observed between the proteins extracts visualised on the SDS-PAGE gel, but protocol P3 gave a higher number of protein bands with an especially good representation of those at high molecular weights.

In order to further assess the quality of the proteins extracted using the three protocols, the extracts were separated on 18 cm pH 3-10 non-linear (nl) IPG strips in the first dimension followed by 12% polyacrylamide gels in the second dimension. The gels were stained with silver, scanned and analysed using the ImageMaster 2DElite software (Figure 2.2A). Only 303 protein spots were detected on the 2D gel run with protein extracted using protocol P1. The protein spots were concentrated mainly between pH 4 and 7 and very few were detected at more basic pH. Detection of spots using ImageMaster 2DElite software on this

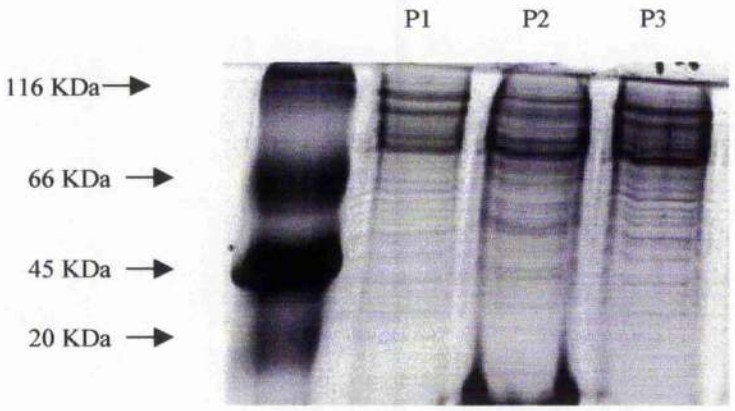

Figure 2.1: SDS-PAGE analysis of proteins extracted using protocols P1, P2 and P3. Proteins from $1x10^8$ procyclic trypanosomes were extracted. The extracts were run on a 17% SDS-PAGE gel to assess the quantity and quality of the extracts. The gel was stained with Coomassie Brilliant blue. Lane 1: broad range molecular weight marker (catalogue number C3437, Sigma).

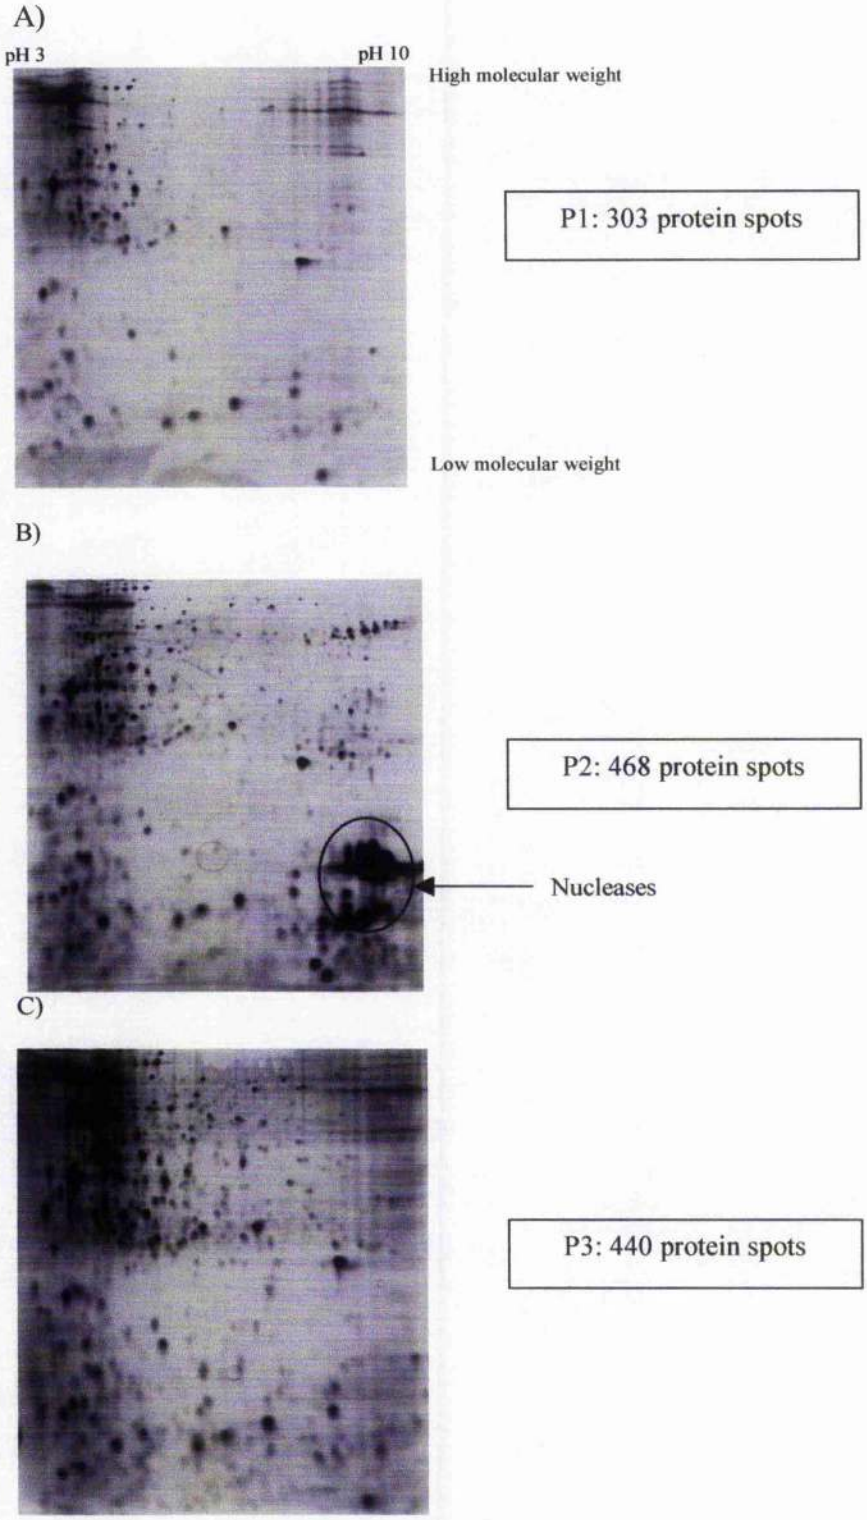

Figure 2.2: 2DE separation of proteins extracted using protocol P1, P2 and P3. Proteins were extracted from $1x10^8$ trypanosomes, separated on broad pH IEF (pH 3-10nL) 2D gels and silver stained. The gels were analysed using ImageMaster 2DElite software to determine the number of protein spots separated.

gel was difficult because of the poor resolution of high molecular weight spots. 468 and 440 protein spots were detected on silver stained 2D gels of proteins extracted using protocols P2 and P3 respectively (Figure 2.2B and C). The resolution on these gels was much higher than for protocol P1. A good representation of low and high molecular weight protein spots as well as protein spots located at acidic and basic pH was observed on these 2D gels. The 2D pattern of proteins extracted using protocol P3 showed horizontal streaking on the gel in the area of high molecular weight proteins. This prevented the complete separation of the protein spots located at this region of the gel. No streaking was observed on 2D gel run with proteins extracted using protocol P2.

Based on theses results, protocol P2, combining the lysis/rehydration buffer with nucleases and protease inhibitors, was the most efficient sample preparation for 2DE analysis of *T. brucei* proteins. For all subsequent analysis, protocol P2 was chosen since the greater number of spots were obtained and were separated with the highest resolution using this sample preparation protocol.

2.3.2 Assessment of the reproducibility of protocol P2

Three independent extractions were undertaken using protocol P2 on different days from different cultures of *T. brucei* 927. The samples were separated by 2DE (pH 4-7) on 18 cm gels. The gels were silver stained and analysed (Figure 2.3). The 2D pattern on the gels was highly reproducible. The intensity of staining of spots also seemed to vary very little between the different extractions.

Proteins from three different concentrations of trypanosomes ($1x10^7$, $1x10^8$ and $1x10^9$) were extracted using protocol P2 and separated by 2DE (pH 3-10nl) to assess the optimal

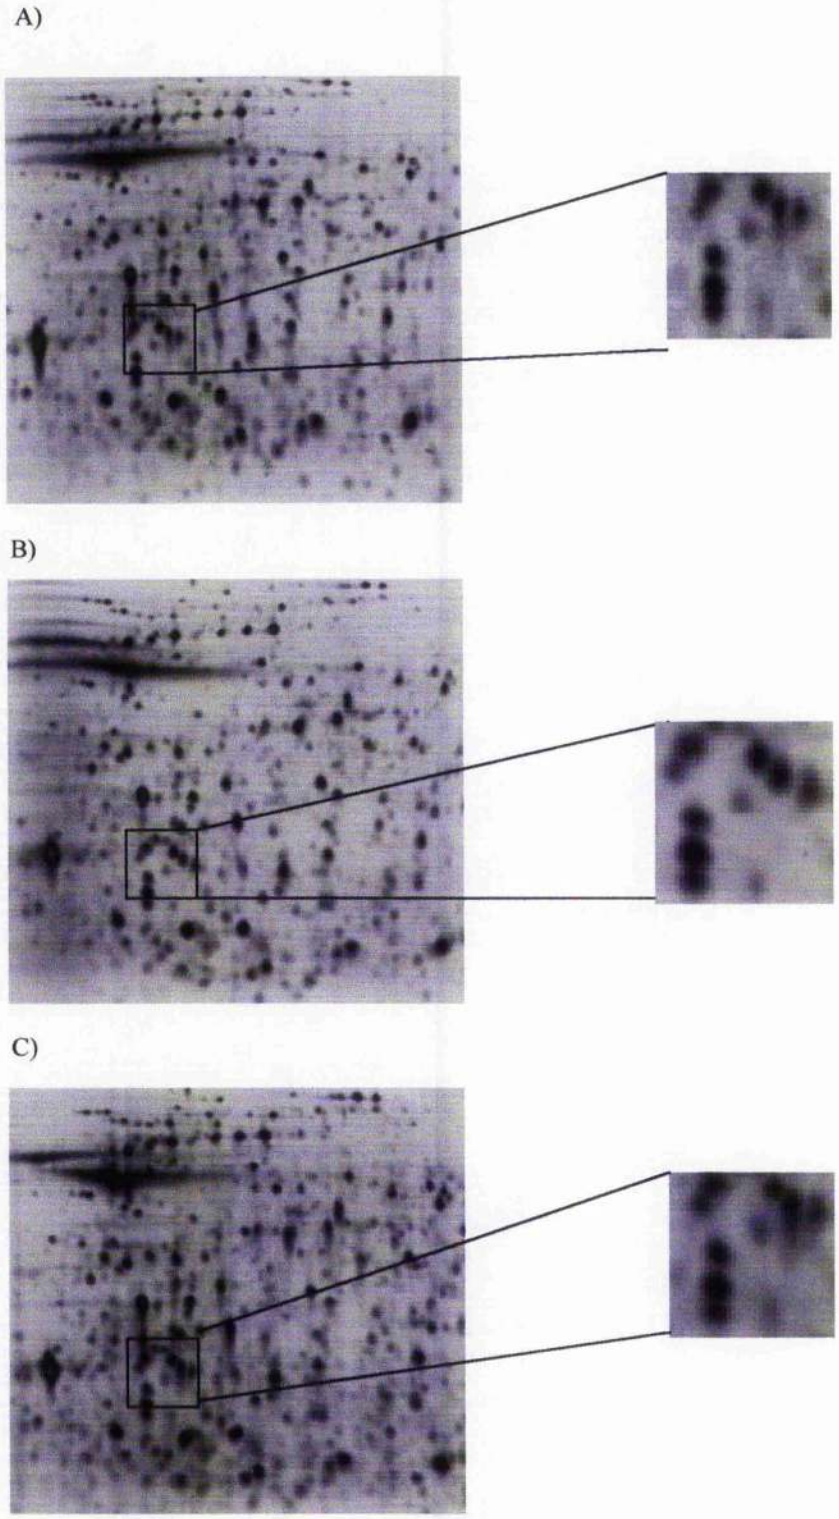

Figure 2.3: 2DE separation of three independent protein extracts using protocol P2. The reproducibility of the sample preparation using protocol P2 was assessed by running three independent protein extracts on pH 4-7 2D gels.

protein concentration for running over 18 cm 2D gels. The gels were silver stained and analysed with the 2DElite software (data not shown). At a concentration of $1x10^9$ trypanosomes (about 4 mg of proteins) horizontal streaking due to protein precipitation was observed, preventing the resolution of the spots. The highest number of protein spots with the best resolution were obtained from extracting proteins from $1x10^8$ trypanosomes, corresponding to about 0.7 mg of proteins, and this concentration was loaded onto gels to be silver stained for the rest of the project.

2.3.3 Comparison of staining techniques for the detection of proteins

One of the major limitations of the 2DE technique is the visualisation of the proteins once they have been separated on 2D gels. Unlike genomics, proteomics has no equivalent of amplification by PCR and thus sensitivity of the staining technique is a critical issue. Three protein stains, Coomassie Brilliant blue, silver and Sypro ruby, were compared for their sensitivity in detecting proteins separated by 2DE.

Proteins were extracted from procyclic trypanosomes using protocol P2, separated on three 18 cm 2D gels, pH 4-7 and the 2D gels were stained with either Coomassie Brilliant blue, silver or Sypro ruby (Figure 2.4). Image analysis of these gels enabled the detection of 909 protein spots on the silver stained gel, 605 protein spots on the Sypro ruby stained gel but only 203 protein spots on the Coomassie Brilliant blue stained gel. Silver staining was the most sensitive of the three stains used in this experiment. The developing of the silver stained gels, using the automatic gel stainer, gave inconsistent results (data not shown) possibly due to variation in water temperature.

Sypro ruby: 605 protein spots

Figure 2.4: **A comparison of protein stains.** Solubilised proteins from procyclic trypanosomes ($1x10^8$) extracted using protocol P2 were loaded onto pH 4-7 gels. The gel images were analysed using the ImageMaster 2DElite software.

2.3.4 Assessment of the extraction of a membrane proteins using protocol P2

Membrane proteins are among the most difficult proteins to solubilise during sample preparation. This characteristic may exclude membrane proteins from the IEF step of 2D gels. Western blot analysis was used to assess the solubilisation and separation of two known *T. brucei* membrane proteins, Rab2 and Rab11, (Field *et al.*, 1999, Pal *et al.*, 2003) using protocol P2 and their separation by both one and two dimensional gel electrophoresis.

Proteins were separated on one dimensional SDS-PAGE gels and Western blotted using antibodies against the Rab2 and Rab11 membrane proteins of *T. brucei*. In addition, proteins were extracted directly from cells by boiling in SDS-PAGE loading buffer. This highly denaturing environment should extract the membrane proteins, and so this extract was used as a positive control. These extracts were run in parallel on SDS-PAGE gels. Coomassie Brilliant blue staining of the gel showed the increased number of protein extracted by boiling the trypanosome pellet in SDS loading buffer as compared with protocol P2 (Figure 2.5). More specifically, high molecular weight proteins were under represented in the protein extracts from protocol P2.

The Rab2 protein was extracted from procyclic trypanosomes by both extraction techniques as shown by Western blot analysis (Figure 2.6A). Western blot analysis with antibodies against the *T. brucei* Rab11 protein was also performed in a similar experiment (Figure 2.6B). No pre-immune serum was available as a control for either antiserum but the absence of binding with anti Rab11 allowed the results to be used as a negative control for Rab2.

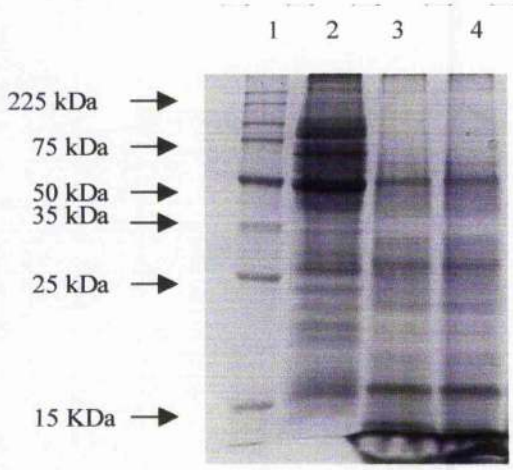

Figure 2.5: SDS-PAGE gel of protein extracted using protocol P2. Coomassie Brilliant blue stained SDS-PAGE gel of protein extracted from line 386. Proteins were extracted by dissolving $1x10^8$ trypanosomes in SDS loading buffer (lane 2) or using protocol P2 developed for 2DE analysis (lane 3 and 4).

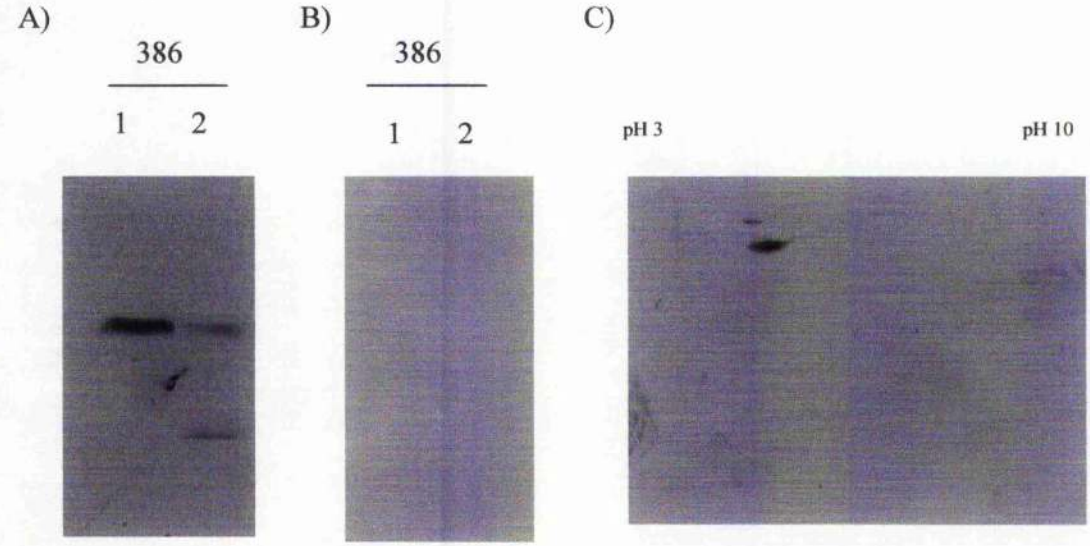

Figure 2.6: Western blot analysis of Rab2 and Rab11 extracted from *T. brucei* and separated by SDS-PAGE gel and 2DE. Proteins were extracted from procyclic forms by either boiling the trypanosome pellet in SDS loading buffer (lane 1) or using protocol P2 (lane 2) developed for 2DE sample preparation. Western blot analysis was performed using affinity-purified rabbit TbRab2 antiserum (A) and TbRab11 antiserum (B) (gift from Dr M. Field, Imperial College London). Whole cell extract from procyclic *T. brucei* 386 was separated by 2DE on a 7 cm pH 3-10nl strip. Western blot analysis was performed using affinity-purified rabbit TbRab2 antiserum (C).

To determine whether the Rab2 protein could be detected on a 2D gel, a 7 cm 2D gel (pH 3-10nl) was run with protein extracted using protocol P2 and analysed by Western blot (Figure 2.6C). The protein spots detected with the anti-Rab2 antibody were resolved as a horizontal streak, from which three protein spots located at similar molecular weight and slightly different pI could be detected within the streak (Figure 2.6C). This demonstrated that the Rab2 protein entered the IPG strip during the IEF separation step, were partially separated by IEF and transferred in the SDS-PAGE gel.

These results would suggest that a combination of chaotropes, zwitterionic amphiphilic compounds and DTT in the sample preparation buffer enables the extraction of at least some membrane proteins and their separation by 2DE.

2.4 Discussion

The "ideal" sample preparation would require extracting all the protein components, including hydrophobic membrane proteins, proteins with extreme pI a well as low copy number proteins in the presence of the most abundant proteins. Disruption of hydrogen bonds by chaotropes, prevention of hydrophobic interactions by surfactants and destruction of intramolecular and intermolecular disulfide bonds by reducing agents are essential in order to obtain a high level of protein extraction and therefore the detection of a maximum number of protein spots by 2DE and to avoid the presence of multiple proteins per spot (Rabilloud, 1998; Molloy, 2000; Lanne *et al.*, 2001). Inclusion of a cocktail of proteinase inhibitors will minimise proteolytic activity and so minimise the generation of multiple different derivatives of each protein.

To achieve this aim, protocols have been developed which include the use of a combination of urea and thiourea (chaotropes) with CHAPS (surfactant), DTT (reducing agent) and a cocktail of protease inhibitors. The addition of nucleases to the lysis/rehydration solution caused an increase in the number of protein spots and a higher resolution of these spots on 2D gels.

The sample preparation protocol needs to be as simple as possible in order to minimise sample variability. In the P2 protocol developed here, all the reagents were added to the trypanosome pellet in one step and the lysis occurred at room temperature. This gave very high reproducibility of 2D patterns from independent extractions.

Global protein expression studies using silver stained pH 4-7 gels demonstrated a variation in the number of resolved protein spots from 630 spots (Cohen *et al.*, 2002) to about 1000 spots (van Deursen *et al.*, 2003). Using the P2 protocol developed in this study 909 protein spots could be detected by silver staining of pH 4-7 gels. , which ranks the P2 solubilisation protocol in the higher range of the protocols used for global expression profiling.

The silver stain was more sensitive for protein detection on 2D gels than either Coomassie Brilliant blue or Sypro ruby. However, silver staining has several drawbacks for 2DE analysis such as a poor reproducibility, a limited dynamic range and the fact that certain proteins stain poorly, negatively or not at all (Lauber *et al.*, 2001). In addition, low detection limits often occur in mass spectrometry because the stain modifies cysteine residues and the glutaraldehyde and formaldehyde used in the procedure alkylate protein amino groups (Patton, 2000). The fluorescent stain, Sypro ruby, was slightly less sensitive

(about 66% of the protein spots detected by silver were detected by Sypro ruby), but was more reproducible and easier to perform. The detection limit of the Sypro ruby dye is in the range of 1-2 ng of protein per spot, and the linear range is over three orders of magnitude (Görg *et al.*, 2000). Consequently Sypro ruby and Coomassie Brilliant blue were the preferred detection techniques for proteomic analysis of *T. brucei*. Sypro ruby being a fluorescent stain rendered the excision of the protein spots of interest from the 2D gels difficult and requires special equipment such as the Amersham Ettan robotic workstation, which was not available at the beginning of this study. Consequently, Coomassie Brilliant Blue staining was used at first to detect highly abundant differentially expressed proteins and Sypro ruby was used in the second pass to determine differentially expressed low abundance proteins.

Two antibodies against Rab proteins were used on Western blot analysis to assess the extraction of membrane proteins using protocol P2 and the of these proteins separation by 2DE. Rab proteins are small GTPases involved in the endocytosis and exocytosis transport in trypanosomes. They control the direction and timing of vesicle fusion during intracellular trafficking between membraneous compartments. Rab proteins are not transmembrane proteins, instead they are peripheral proteins thought to be embedded in the membrane through their isoprene moieties. Rab2 is restricted to endoplasmic reticulum (ER) exit sites and ER-Golgi intermediate compartments (Field *et al.*, 1999) while Rab11 is located in the endosomal system and co-localises with internalised anti-VSG antibody and Transferrin (Pal *et al.*, 2003). The Rab2 protein was shown to be extracted by protocol P2 and to separate by 2DE. No detection of Rab11 protein could be obtained in either the sample extracted by protocol P2 or the sample obtained by boiling the trypanosome pellet in SDS buffer. Rab2 is known to be expressed at similar levels in procyclic and

bloodstream forms of *T. brucei* whereas the Rab11 protein is strongly up regulated in bloodstream trypanosomes (Field and Field, 1997; Pal *et al.*, 2003). As the samples used in this study were extracted from procyclic trypanosomes, the level of Rab11 proteins might have been too low to be detected. This experiment was performed to assess the extraction of membrane proteins by the solubilisation protocol developed. As Rab proteins are peripheral proteins, it is possible that the Rab2 protein detected in the 2DE extract was due to the detachment of the Rab protein from its isoprene moiety. Transmembrane proteins are the most difficult membrane proteins to solubilise as they contain hydrophobic regions that enable part of the protein to reside within the membrane. Extraction of transmembrane protein from *T. brucei* could be performed using anti-cystein-rich transmembrane protein (anti-CRAM) antibodies (Liu *et al.*, 2000). CRAM protein is located at the flagellar pocket and is involved in the endocytosis pathways and has been shown to be expressed in procyclic forms of trypanosomes (Liu *et al.*, 2000). As such this protein would be a good test to determine the extraction of transmembrane proteins by protocol P2.

The main aim of the work described in this chapter was to develop a simple, complete and reproducible method for sample preparation from *T. brucei*. This was achieved by comparing the proteins extracted using three different protocols followed by analysis on SDS-PAGE gels and 2D gels. Sample preparation P2 was shown to be simple, reproducible and robust, and it enabled the extraction of at least some membrane proteins, so that 2D gels of *T. brucei* proteins can now be run reproducibly. The protein spots of interest can then be analysed by mass spectrometry techniques to generate information about the protein spots. The mass spectrometry data can then be used for identification of the protein spot as described in the next chapter.

Chapter III

Assessment of algorithms for protein identification from peptide mass fingerprint data

3.1 Introduction

In the previous chapter a simple, efficient and reproducible sample preparation method was developed for 2DE analysis of protein extracted from procyclic forms of *T. brucei*. The next step, after separation of proteins by 2DE, is the identification of the proteins of interest by mass spectrometry (MS).

Various mass spectrometry techniques are available (peptide mass fingerprint, peptide sequence tags) for the identification of protein spots from 2D gels. The simplest and fastest method is peptide mass fingerprinting (PMF) which can be powerful when combined with a protein sequence database. A peptide mass fingerprint consists of the mass of each peptide generated from digestion of a protein with a specific protease as measured by mass spectrometry. A peptide mass fingerprint provides no inherent sequence information. The commonly used enzyme for digestion of proteins is trypsin which specifically cleaves the peptide bond at the C-terminus of arginine and lysine residues, except if they are followed by a proline. Peptide mass fingerprints are generated by Matrix-Assisted-Laser-Desorption-Ionsation Time-Of-Flight (MALDI-TOF) mass spectrometry. The use of peptide mass fingerprints generated from mass spectrometry for protein identification was first demonstrated in 1993 for cytochrome c from dog and pigeon, a GTP-binding protein from humans, an uteroferrin from pig, the human sex steroid binding protein and a thermostable DNA polymerase (Yates *et al.*, 1993).

Search engines have been developed to enable the rapid searches of protein and nucleotide sequence databases with PMF data. Three common steps are involved for all search engines: firstly, each protein in the database is digested *in-silico* based on the specificity of the enzyme and the masses of the resulting peptides are calculated enabling the construction of a theoretical peptide mass fingerprint; secondly, the experimentally determined peptide mass fingerprint is compared with the theoretical peptide mass fingerprint and a score is calculated which reflects the accuracy of the match between the experimental and theoretical peptide masses; thirdly, the protein sequences in the database are sorted according to their score and the protein sequence with the best score is selected (Fenyö, 2000).

All search engines developed for protein identification by PMF are based purely on a statistical approach. With the increased use of proteomic analysis, several types of search engine for protein identification by PMF have been developed and made available on the Internet (Table 3.1). All are based on the same principle: the comparison of a peptide mass fingerprint generated from a protein with the theoretical peptide mass fingerprint of all available proteins in a database (Fenyö, 2000). Each new generation of search engine has been improved by increasing the sensitivity and specificity of the protein identification. The sensitivity of a search engine can be defined as its ability to detect a match in the database, whereas its specificity is the ability to distinguish random from real matches. The main improvement made to these search engines in recent years has been the addition of algorithms for evaluating the search results. The most important aspect of the search algorithm is the need to distinguish a correct identification from a random match: i.e. specificity.

Table 3.1: List of search engine available for protein identification from peptide mass fingerprint data.

The only comparison of the various algorithms for the identification of protein using PMF data found in the literature was performed *in-silico,* using theoretical protein sequences from NCBInr cleaved using trypsin cleavage rules to obtain a random peptide monoisotopic mass pool (Tang *et al.*, 2000). This study was performed on three search engines (MS-Fit, ProFound and MASCOT®) and demonstrated a wide variation between the sensitivity and specificity of the search engines. This comparison does not appear to have been performed on real proteins separated by 2DE, digested with trypsin and analysed by MS.

In this study, 126 peptide mass fingerprints, generated by MALDI-TOF MS from *T. brucei* proteins separated by 2DE, were used to evaluate the specificity of three publicly available search engines. The MS-Fit, MASCOT® and ProFound search engines were used to search the National Centre for Biotechnology Information protein database (NCBInr). The evaluation of the sensitivity and specificity of the three search engines for the identification of proteins from *T. brucei* was performed by comparing the results obtained for each peptide mass fingerprint.

3.2 Materials and Methods

3.2.1 Commonly used reagents

Ammonium bicarbonate, TFA, CHCA and acetonitrile were purchased from Sigma. Trypsin was purchased from Promega. The ZipTip™ pipette tips were purchased from Millpore.

3.2.2 Protein extraction, 2DE and staining

Proteins were extracted from $2x10^8$ procyclic trypanosomes from line 927 according to protocol P2 developed in chapter 2. The proteins were separated by 2DE and stained using Coomassie Brilliant blue following the protocols described in chapter 2.

3.2.3 In-gel trypsin digestion and mass spectrometry

Gel pieces were excised from the gel using a scalpel and transferred into an Eppendorf tube. The gel pieces were washed for 1 h 30 min in 100 mM ammonium bicarbonate, 1 h 30 min in 50% acetonitrile/100 mM ammonium bicarbonate, then 10 min in 100% acetonitrile and then dried in a vacuum centrifuge. The gel pieces were rehydrated with 0.2 µg of trypsin in 25 mM ammonium bicarbonate for 15 min. In-gel digestion was carried out overnight at 37°C, on a horizontal shaker at 1,000 g (Hellman *et al.*, 1994).

The resulting peptides were desalted and concentrated using ZipTip™ pipette tips containing C_{18} reverse phase media. The samples were acidified by addition of 3 µl of 3% trifluoroacetic acid (TFA) prior to desalting. The ZipTip™ was equilibrated in 50% acetonitrile by aspirating 10 µl into the tip twice and then washing twice with 10 µl of 0.1% TFA. Peptides were then bound to the reverse phase and washed twice with 0.1% TFA. Peptides were eluted in 2 µl of 50% acetonitrile/ 0.1% TFA (Erdjument-Bromage *et al.*, 1998, Lamer and Jungblut, 2001).

The concentrated desalted sample (0.5 µl) was mixed with 0.5 µl of matrix solution (10 mg/ml α-cyano-4-hydroxycinamic acid (CHCA) in 50% acetonitrile/ 0.1% TFA), spotted onto a stainless steel plated MALDI sample stage, and allowed to air-dry for 30 min. Spectra were acquired using the PerSpective Biosystems Voyager-DE instrument in

reflector/delayed extraction mode. Peptides are co-crystallised with the matrix, a small weakly acidic molecule, which absorbs the energy from the laser and emits energy as heat. This results in the desorption of samples which are then accelerated into the vacuum. Since all ions are accelerated from a fixed point with the same potential, they will drift according to their mass to charge ratio. Calibration was achieved using the porcine trypsin auto-digestion peptides at 842.510 and 2211.1046 Da $[M+H]^+$. Composite spectra consisting of 200 laser shots were acquired for each protein spot.

3.2.4 Protein identification search engines

3.2.4.1 First generation algorithm: MOWSE

The first generation of algorithms developed for the use of PMF for protein identification were based on the simplest and most obvious scoring method, which is to count the number of measured peptide masses that correspond to calculated peptide masses in the theoretical peptide mass fingerprint of each protein in the database (Pappin *et al.*, 1993). This is referred to as the MOlecular Weight SEarch (MOWSE) score. The greater the number of experimental peptides matching the theoretical data, the higher the likelihood of the protein in the database being the protein excised from the gel. This technique was shown to work well for high-quality experimental data. However, it has the disadvantage that it usually gives higher scores to larger proteins as these have a larger number of proteolytic peptides and so the probability of random matching is higher. This is referred to as the protein size effect.

3.2.4.2 Second generation algorithm: the MS-Fit search engine

The MOWSE score implemented in the MS-Fit search engine (http://prospector.ucsf.edu/ucsfhtml4.0/msfit.htm) is based on the simple scoring method described above. However, the MOWSE score has been improved to compensate for the

protein size effect and also to take into account the relative abundance of the peptides in the database when calculating the score, that is, the probability of getting a random match to a larger peptide is lower and therefore a match will contribute to a higher degree to the score (Fenyö, 2000). From the literature, MS-Fit is the search engine most often employed for protein identification using PMF data, however, the scoring system employed by MS-Fit is un-reliable due to a poor scoring system and so many authors have developed their own criteria. The criteria selected for this study for the unambiguous identification of *T. brucei* protein spots using the MS-Fit search engine were as follows:

a) At least five peptides from the measured peptide mass fingerprint must match those of the theoretical peptide mass fingerprint of the protein in the database
b) The size of the peptides masses matching the theoretical peptide mass fingerprint should cover at least 15% of the protein
c) The accuracy of the matching peptides should be equal to or less than 50 ppm (differences between the measured peptide and the theoretical peptide should be lower than 50 ppm) (Mann *et al.*, 2001).

These three criteria were applied to the MS-Fit search results and used as an alternative to the MS-Fit scoring system to determine protein identification. They were considered to provide high stringency thresholds limits for unambiguous protein identification.

3.2.4.3 Third generation algorithms: the MASCOT® and the ProFound search engines

The MASCOT® search engine

The MASCOT® search engine (http://www.matrixscience.com) is based on a modified MOWSE algorithm using a probability based scoring system. The probability that the observed match between the experimental data and a protein sequence is random is

calculated for each protein sequence in the database. The proteins are classified with increasing probability of being a random match to the experimental data. In addition, the probability that a match would be significant is calculated by the search engine. This probability is based on the size of the database and the frequency of each peptide mass in the database. The MASCOT® search engine guidelines state that if the probability based score is higher than the database's probability (p) then the match is significant within 95% confidence limits. The scores are expressed as $-10*\log(P)$, where P is the probability that the observed match is a random event (Perkins *et al.*, 1999). The results are displayed as a histogram showing the distribution of the scores and the 95% confidence limit (p).

The ProFound search engine

The ProFound (http://129.85.19.192/profound_bin/WebProFound.exe) search engine also contains a probability based scoring system. The probability of the match being the best match is calculated based on Bayesian theory (Tang *et al.*, 2000). This probability takes into account available information about each individual protein sequence in the database (e.g. molecular weight, pI) and allows for the incorporation of additional experimental information (e.g. amino acid composition or sequence information). In addition, empirical information about patterns observed for the distribution of proteolytic peptides along the protein sequence is included in the algorithm (Tang *et al.*, 2000).

Database searches by the ProFound search engine can be divided into four steps:

1) assignment of mono-isotopic masses to the raw data
2) peptide mass search against the database
3) Bayesian probability calculation (P value)
4) significance testing of the results (Z score)

Bayesian probability increases with increasing number of peptide matches, increasing mass accuracy and decreasing number of digested fragments. The Bayesian probability gives a

measure of confidence that the protein selected by the algorithm from the database is the sample protein (Zang *et al.*, 1995).

The ProFound search engine also incorporates an algorithm that estimates the significance of the match (Z score) for each candidate protein. Significance testing is achieved through calculation of a score frequency function for random matches. This is derived from statistical analysis of the database being searched using random selections of peptide masses from different proteins that are then grouped as synthetic proteins and used in a peptide mass search of the database. Therefore the Z score gives an indication of how significantly different the identified protein is compared to a random mass match in the database (Ericksson *et al.*, 2000). A Z score ≥ 1.65 indicates that the candidate protein in the database is unlikely (within 95% confidence) to be a random match (Zang *et al.*, 2000). Based on the properties of this search engine, the protein with the highest P value and Z score is identified as the most likely candidate protein.

3.3 Results

Peptide mass fingerprints of *T. brucei* proteins separated by 2DE were generated by MALDI-TOF MS. These were analysed using three search engines: MS-Fit (ProteinProspector), MASCOT® (MatrixScience) and ProFound (Rockefeller). The three search engines were used to compare experimental peptide mass fingerprints against theoretical peptide mass fingerprints generated from all available protein sequences in the NCBInr database. Search parameters were selected to accommodate the three search engines and the same parameters were used throughout the searches (Table 3.2). The data entry form for each search engine were very similar. The entry form of the MASCOT® search engine is given as an example (Figure 3.1). Note that all search engines for protein

Parameter	Selected option
Database	NCBInr
Enzyme	Trypsin
Protein mass range	0 to 3000 KDa
Tolerance	50 ppm
Missed cleavage	1
Fixed modification	Carboxymethylation
Variable modification	Oxidation of methionine
Charge state	MH^+

Table 3.2: **Parameters selected for database searches using MS data**. These parameters were used with MS-Fit, MASCOT® and ProFound search engines.

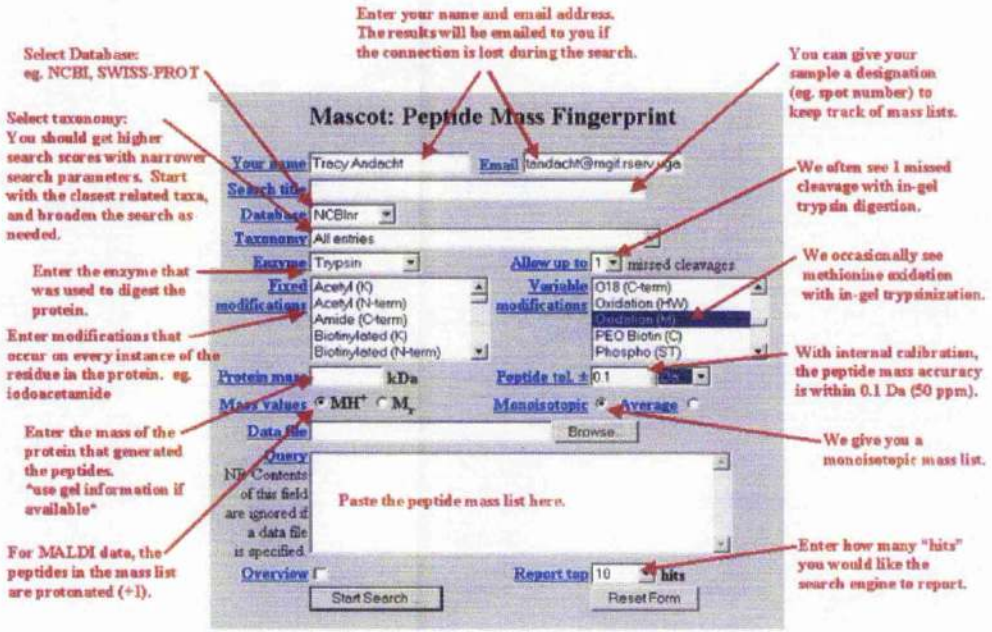

Figure 3.1: **Web page of the MASCOT® search engine.**
Reproduced from http://www.matrixscience.com/cgi/searchform.pl?SEARCH=PMF

identification using PMF data will give a "best match" candidate even if all the matching peptides are random matches. It is essential to distinguish between a significant match and a best match. This can be achieved by evaluating the specificity of the algorithms used in the search engines.

3.3.1 Searching the NCBInr database with MS-Fit, MASCOT® and ProFound search engines

126 peptides mass fingerprints were generated by MADLI-TOF MS from *T. brucei* proteins separated by 2DE. These were searched against the NCBInr database using three search engines: MS-Fit, MASCOT® and ProFound.

3.3.1.1 The MS-Fit search engine

In total, 37 protein spots were identified using the three criteria described in Materials and Methods. These proteins had a corresponding MOWSE score ranging from 10^{+3} to 10^{+10} (Table 3.3). However, 13 additional protein spots with a MOWSE score higher than 10^{+3} did not reach the threshold limits fixed by the three criteria for unambiguous identification, i.e. percentage of coverage < 15% (data not shown). This confirmed that the MOWSE score implemented in MS-Fit could not be used on its own with confidence for unambiguous protein identification by PMF. In total, 30% of the peptide mass fingerprints searched using the MS-Fit search engine (37 out of 126) reached the threshold limits set by the three criteria and were considered to be identified.

3.3.1.2 The MASCOT® search engine

The MASCOT® search engine's guidelines state that a protein score above the database score (p) would give an unambiguous identification within 95% confidence limits. This guideline was applied to the identification of the proteins from *T. brucei* and enabled the

Table 3.3 Results from the MS-Fit, MASCOT® and Profound search engines. The samples highlighted in yellow correspond to the spots identified by the ProFound search engine using its probability based scoring system. The samples highlighted in blue correspond to the spots identified within 95% confidence limits using the MASCOT® search engine.

identification of 16 protein spots, corresponding to 12.7% of the total peptide mass fingerprints analysed (Table 3.3).

3.3.1.3 The ProFound search engine

The ProFound search engine is implemented with a probability scoring system (P) and a significance testing system (Z). The threshold values given by the ProFound search engine for identification are a P value of 1 and a Z score above 1.65. These threshold values corresponded to an identification within the 95% confidence limits. These threshold values were used for the identification of *T. brucei* protein spots separated by 2DE and enabled the identification of 19 spots (Table 3.3). This represented 15% of the total protein spots analysed.

3.3.2 Comparison of the results obtained from the three search engines

An analysis of the specificity of algorithms implemented in the search engines can be made by submitting the same search to multiple search engines and comparing the results. This analysis was undertaken with the three search engines using peptide mass fingerprints generated from *T. brucei* protein spots separated by 2DE.

As the MS-Fit search engine had no reliable scoring system implemented in the search engine, the three criteria employed as threshold for unambiguous protein identification for the MS-Fit search engine were applied to the MASCOT© and the ProFound search engines. The best score obtained for the peptide mass fingerprints reaching the thresholds limits set by the three criteria were compared for each search engine. Using the three criteria, 29.4% of the peptide mass fingerprints analysed (37 out of 126) were identified using the MS-Fit search engine, but only 27.7% (35 out of 126) were identified using the MASCOT® search

engine and 21.4% (35 out of 126) were identified using the ProFound search engine (Table 3.4). A comparison of the three criteria used for identification showed that the differences in the results between the search engines were due to the percentage of coverage of the protein in the database (Table 3.3). The percentage was calculated directly by the search engines. For the same protein, the percentage of coverage varied from 1 to 5% between search engines. As a threshold of 15% coverage was needed for unambiguous identification, any difference in coverage calculated by the search engines meant that a protein accepted as unambiguously identified by one search engine was not identified with another. This demonstrated how critical the threshold limits set by the user became when there is no probability based scoring system used in the search engine. All search engines agreed on the name and NCBI accession number (gi number) of the best score for each peptide mass fingerprint searched, demonstrating that the three search engines had similar sensitivity.

When the probability based scoring system of the MASCOT® and the ProFound search engines was used to determine unambiguous identification only 15.8% (20 protein spots) and 12.7% (16 protein spots) were unambiguously identified respectively. The probability based search engines had a higher specificity than the three criteria used with the MS-Fit search engine.

	MS-Fit	ProFound	MASCOT®
Number of protein identified based on the scoring system of the search engine	N/A	20	16
Number of protein identified using the criteria of mass accuracy, number of matching peptides and coverage of the protein	37	35	35

Table 3.4: Summary of comparison of the results from the MS-Fit, MASCOT® and ProFound search engines. Results were obtained searching the NCBInr database with the 126 peptide mass fingerprints. The number of proteins identified by the three search engines using the scoring system and the three criteria described in the text are shown. N/A non-applicable.

3.4 Discussion

The sensitivity and specificity of the search engine together with human judgment are the three key factors in the identification of proteins by mass spectrometry. The sensitivity of a search engine relates to its ability to detect a match in a given database while the specificity relates to its ability to determine whether the match is significant (random match versus real match). Three search engines were compared for their sensitivity and specificity in protein identification by PMF. The MS-Fit search engine was one of the first developed to search databases with peptide mass fingerprints. A high score with the MS-Fit search engine (10^{-3}) did not always correspond to an unambiguous identification with the MASCOT® and the ProFound search engines. The low specificity of the MS-Fit scoring system means that the user needs to rely on judgment to accept or reject the best score as reflecting an unambiguous protein identification.

The MS-Fit search engine has been the favoured search engine for protein identification by PMF in many proteomic studies. The criteria used as threshold limits for protein spot identification employed varied remarkably, from the simplest criteria of five peptides matching to the protein in the database (McAtee *et al.*, 2001), through a minimum of 30% coverage (Jungblut *et al.*, 1999) up to a combination of criteria such as four peptides matching with an accuracy of at least 40 ppm (Smolka *et al.*, 2003). Basing the identification on the percentage of protein covered by the measured peptides biases the identification process towards small proteins, whereas an identification process based solely on five peptides matching a protein biases the identification towards large proteins.

The selection of criteria for unambiguous identification of proteins can be difficult. The accuracy obtained in the measurement of peptide masses strongly influences the specificity

of the search. Investigation of the role of accurate mass measurement in protein identification strategies demonstrated that random matches could occur for proteins matching as many as 15/23 peptides while using a range of 1,000 to 2,000 ppm (Clauser *et al.*, 1999). When dropping the mass accuracies in the range of 100 to 500 ppm, the level of random matches appeared to fall to 7/23 or 8/23 peptides respectively. Once the accuracy level reaches 50 ppm, currently possible with MALDI-TOF in reflector mode using internal calibration, the level of random matches dropped to 6/23 peptides (Clauser *et al.*, 1999). Recent calculations for proteins expressed by the genomes of *Escherichia coli* and *Saccharomyces cerevisia* indicate that at 0.1 ppm mass accuracy, 96% of the proteins will generate tryptic peptides with one or more unique masses (Figure 3.2). The remaining 4% correspond to gene products that are largely duplicates of other proteins (Bruce *et al.*, 1999). However, this level of mass accuracy is not achievable with MALDI-TOF MS. Consequently, a combination of criteria including the accuracy of the peptide match (50 ppm), the number of tryptic peptides matching (5) and in addition a limit of the coverage obtained from the proteins (15%) were used as threshold limits with the MS-Fit search engine for unambiguous identification of proteins (Mann *et al.*, 2001). However, even these stringent criteria were shown to be too relaxed compared to the probability-based scoring systems of the ProFound and the MASCOT® search engines. This demonstrated the importance of the implementation of a probability-based scoring system, removing the "human" factor for protein identification. The advantage of a probability based scoring is that a simple rule can be used to judge whether a result is significant or not. The addition of a scoring system determining the probability of the best match being a significant match is essential. It should be kept in mind that the significance testing can never definitely prove whether a result is true or false. The significance level is just the calculated risk of obtaining a false result.

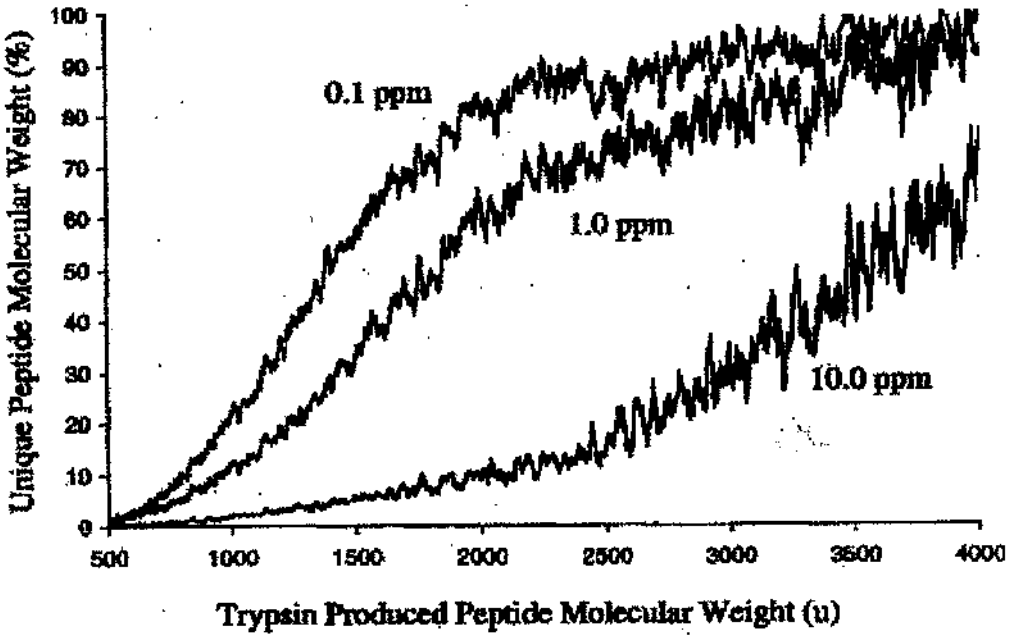

Figure 3.2: Importance of mass accuracy in protein identification. Graphical representation of all possible unique peptide molecular weights, after trypsin digestion, of all yeast proteins in the NCBI at a mass accuracy of 0.1, 1.0 and 10 ppm (reproduced from Goodlett *et al.*, 2000).

All search engines are based on the assumption that the protein being analysed is present in the database. However, this assumption is not always true. Consequently, it should be kept in mind that peptide mass fingerprint can only provide the statistically most probable identification, taking into account the state of the database at the time of the search. Even with the most sensitive and selective search algorithm, if the protein sequence is not present in the database then the algorithm's best score will at best be a closely related protein or a random match.

A comparison of the algorithm used in MS-Fit, MASCOT® and ProFound search engines, performed *in silico*, on four proteins sequences taken from NCBI database demonstrated that the algorithm employed by the ProFound was more specific than that used by the MASCOT® which in turn was more specific than the MS-Fit search engine (Tang *et al.*, 2000). The specificity of the ProFound search engine was also shown in this paper to be more consistent over a wider range of protein molecular weight (50 to 200 kDa) than the MASCOT® search engine which was only reliable up to 100 kDa. Trypsin digestion of protein spots is expected to give rise to peptide fragments of between 800 and 2,500 amino acids, depending on the distribution of the recognition sequence for trypsin in proteins (Aebersold and Goodlett, 2001). Consequently the limitation of the specificity of the MASCOT® search engine for large masses should not affect its efficiency for protein identification by PMF.

The MASCOT® search engine was shown to be both sensitive and specific for the identification of proteins from *T. brucei*. In addition the search engine is simple to use and the output of the results easy to interpret. The MASCOT® search engine can also be used for searching databases with Tandem mass spectrometry data. As MALDI-TOF and

Tandem mass spectrometry will both be used in the proteomic study of the mechanism of Cymelarsan resistance in *T. brucei* the MASCOT® search engine was selected for the rest of the proteomic analysis. Other limitations, independent of the search engines (i.e. database, post-translational modifications) in the identification of protein spots by mass spectrometry will be discussed in the next chapter.

Chapter IV
A proteome map of *T. brucei*

4.1 Introduction

The first step in proteomic analysis is the extraction and separation of proteins from trypanosomes by 2DE (chapter 2). Individually separated proteins are excised from the gel and digested with a sequence specific protease (e.g. trypsin). The masses of the proteolytic peptides are measured by mass spectrometry. A search engine is then used to search a database with the data obtained by mass spectrometry (refer to chapter 3). Many types of search engines are available. A comparison of algorithms implemented in three search engines (MS-Fit, ProFound and MASCOT®) demonstrated the sensitivity and selectivity of the MASCOT® search engine (chapter 3). The MASCOT® search engine was purchased from MatrixScience and adapted to search the NCBInr database and a local *T. brucei* database.

Proteomic expression profiling of protozoan parasites was rare, until recently, mainly due to the lack of genome sequences for parasites in general. The limited availability of genome sequence meant that proteins of interest separated by 2DE might not be represented in the database and consequently the protein spots could not be identified using mass spectrometry data. However, the situation is rapidly changing with the publication of the *Plasmodium falciparum* genome sequence (Gardner *et al.*, 2002) and full genome sequencing projects are underway for *T. brucei*, *T. vivax*, *T. congolense*, *Leishmania major*, *Leishmania infantum*, *Toxoplasma gondii*, *Babesia bovis*, *Theileria parva*,

Theileria annulata and a further six plasmodium species (http://www.sanger.ac.uk/Projects/Protozoa and http://wwwtigr.org/tdb/parasites/).

The haploid genome size of *T. brucei* is about $3.5x10^7$ base pairs with 11 homologous chromosome pairs and additional intermediate and mini-chromosomes of uncertain ploidy (El-Sayed *et al.*, 2000). The 11 megabase chromosomes are thought to contain most, perhaps all, the housekeeping genes and so were targeted by the Sanger and the TIGR centres for the sequencing of the *T. brucei* genome, using the 927 stock. The TIGR centre was allocated the sequencing of chromosomes II to VIII while the Sanger centre was in charge of the sequencing of chromosomes I, IX, X and XI. The methods employed by each centre for the sequencing of the chromosome are different. At the Sanger centre, chromosomes were separated by pulsed field gel electrophoresis, excised from the gel and sheared into 2-4 kb fragments which were inserted into a plasmid vector. The clones were then randomly end-sequenced, producing a 8-10x coverage of the chromosome. This technique is called whole chromosome shotgun sequencing. The TIGR centre produced a large number of BAC clones (bacterial artificial chromosome vector pBACe3.6, average insert size of 145 kb) and end-sequenced them. Chromosome specific BACs were selected using cDNA markers specific to the target chromosome, subcloned into plasmid and then sequenced to completion. Then the database of end-sequences was then searched to retrieve BAC clones that overlap by only 5 to 10 kb, and these are then sequence to completion. To date, the sequences of two of the 11 chromosomes have been completed and annotated (data are available on the Internet at http://www.tigr.org/tdb/mdb/tbdb/ and http://www.sanger.ac.uk/Projects/T_brucei/) (Table 4.1).

Sequencing centre	Chromosome	Size (Mb)	Status
Sanger	I	1.15/1.2	Complete
TIGR	II	1.25/1.3	Complete
TIGR	III	1.62/1.75	In progress
TIGR	IV	1.62/1.75	In progress
TIGR	V	1.68/1.75	In progress
TIGR	VI	1.7/2.0	In progress
TIGR	VII	2.1/2.1	In progress
TIGR	VIII	2.1/2.2	In progress
Sanger	IX	3.3/3.5	In annotation
Sanger	X	4.4/4.4	Finishing
Sanger	XI	5.2/5.2	In shotgun

Table 4.1: Genome sequencing project for *T. brucei*. Status of the genome sequencing project for *T. brucei* TREU 927 line, dated 26th June 2003 (reproduced from http//:www.sanger.ac.uk/Projects/T_brucei/progress.shtml). The local *T. brucei* database was made of translated sequences from the available nucleotide sequences from the 11 chromosomes. The size of the chromosomes was estimated by pulsed field gel electrophoresis.

In addition, expressed sequence tags (ESTs) made from the sequencing of randomly selected complementary DNA (cDNA) are also available from EST discovery projects. There are over 5,000 ESTs from *T. brucei* deposited in Genbank, each with a unique accession number, which represent 3,113 unique sequences (Djikeng *et al.*,1998; El Sayed *et al.*, 1995). This sequence information, provided both by the sequencing centres and the EST projects, is essential for the identification of proteins extracted from *T. brucei* and analysed by proteomic techniques.

It is estimated that the trypanosome genome contains approximately 8,000 genes based on sequence from chromosome I and II (Hall *et al.*, 2003; El-Sayed *et al.*, 2003), and while numerous post-translational modifications are known to exist in this organism, the genes in general have no introns, with the exception of the PAP gene (Mair et al., 2000). In addition, RNA editing in trypanosomes has been shown to be extensive for mitochondrial mRNAs which are encoded maxicircles (Madison-Antenucci *et al.*, 2002) but almost non-existent, except for the addition of the spliced leader sequence at the 5'end by trans-splicing, for mRNAs encoded from the 11 chromosomes. Thus unlike in higher eukaryotes, the proteome of trypanosome should not contain a drastically higher number of proteins than genes.

While the current data support the view that intron and alternative splicing do not occur in *T. brucei* and the main factor generating multiple protein product from single genes is likely to be post-translational modification, this has yet to be experimentally tested. In order to test the limitations of the incomplete genome sequence with regard to full proteomic analysis of *T. brucei*, a small scale proteome map was constructed. In addition,

the question of the level of post-translational modification of proteins and the relationship between polypeptide profile and gene number were also addressed.

4.2 Materials and Methods

4.2.1 Protein extraction, 2DE and staining

Whole soluble proteins were extracted from $2x10^8$ procyclic forms of the reference line 927 using protocol P2 as described in chapter 2. Protein extracts were separated by 2DE poly-acrylamide gels using broad pH ranges (pH 4-7 and 6-11) and stained with Coomassie Brilliant blue as described in chapter 2.

4.2.2 In-gel trypsin digestion and mass spectrometry

Protein spots were excised from the gel, digested with trypsin and PMF were acquired using the MALDI-TOF MS as described in chapter 3.

4.2.3 Database searches using the MASCOT® search engine

The "all taxa" category of the NCBInr database and a local *T. brucei* database were searched using the MASCOT® search engine. The parameters selected for the searches are described in chapter 3 (Table 3.2).

4.2.3.1 The NCBInr database

This database contains the translated protein sequences from the entire collection of annotated DNA sequences kept at GenBank, and also protein sequences in the Protein Data Bank (PDB), SWISS-PROT and Protein Information Resource (PIR) databases, covering most of the publicly available data.

4.2.3.2 The local *T. brucei* databases

The local *T. brucei* database was constructed by downloading all available sequence information from ftp sites of the Sanger and the TIGR centres. Two databases were made: a nucleotide sequence database (Pawel_nt) and a peptide sequence database (Pawel_aa). Pawel_nt database consisted of a conglomerate of three nucleotide databases:

1- A genomic database from the TIGR centre containing 60 very long contigs from chromosomes II-IX. These were arbitrarily cut into 222 fragments of manageable sizes for the MASCOT® search engine, comprising fragments of up to 50 kb in length with 600 bp overlap between fragments.

2- Sanger nucleotide genomic data from chromosomes I, IX, X and XI. Chromosome I consisted of one contig which was cut into 22 fragments, chromosome IX comprised 257 contigs and were cut into 317 fragments, chromosome X contained 427 contigs which were cut into 485 fragments and chromosome XI consisted of 896 contigs.

3- *T. brucei* GSS/EST clusters from the Sanger centre containing 20,493 sequences.

Pawel_aa corresponds to the predicted putative genes from genomic data described in 1 and 2. This corresponds to 6,920 sequences from chromosome II-IX from TIGR, 509 sequences from chromosome I, 2,348 sequences from chromosome IX, 10,590 sequences from chromosome X and 2,568 sequences from chromosome XI from the Sanger centre. In total, Pawel_aa contained 22,935 sequences as updated on the 21/06/2003. These databases were downloaded and adapted for searches with the MASCOT® search engine by Dr Pawel Herzyk (University of Glasgow).

4.3 Results

4.3.1 Efficiency of peptide mass fingerprinting

In order to produce a proteomic map of the procyclic form of the reference line 927 whole soluble cell extracts were separated on pH 4-7 and pH 6-11 2D gels (Figure 4.1). A total of 203 protein spots were detected on pH 4-7 gel and 74 protein spots on pH 6-11 gel. From these 2D gels, 126 protein spots were excised (91 protein spots from pH 4-7 gel and 35 protein spots from pH 6-11 gel), in-gel digested with trypsin and peptide mass fingerprints were acquired using MALDI-TOF. The peptide mass fingerprints were searched against the NCBInr and the local *T. brucei* database using the MASCOT® search engine, enabling the identification of 51 protein spots. The list of peptide masses obtained for each protein spot and used to search the databases is given in Appendix I.

In total, 40.5% of the peptide mass fingerprints obtained using MALDI-TOF (51 out of 126 protein spots) were matched to a protein in either the NCBInr database or the local *T. brucei* databases (Table 4.2). The criteria for identification with the MASCOT® search engine were that the protein score had to be higher than the database score (p). From the 51 protein spots identified, 17 peptide mass fingerprints matched onto a *T. brucei* entry in the NCBInr database. In addition, 24 peptide mass fingerprints matched only to proteins in the local *T. brucei* database. Most of the proteins in the local *T. brucei* database are not annotated so a BLASTp search was performed against the NCBInr database to identify homologous sequences. From the 24 proteins identified in the local database, seven sequences had no homologues in the NCBInr database; these are referred to as hypothetical proteins in Table 4.2. Detailed results from the MASCOT® search engine for each protein spot analysed by PMF are given in Appendix II.

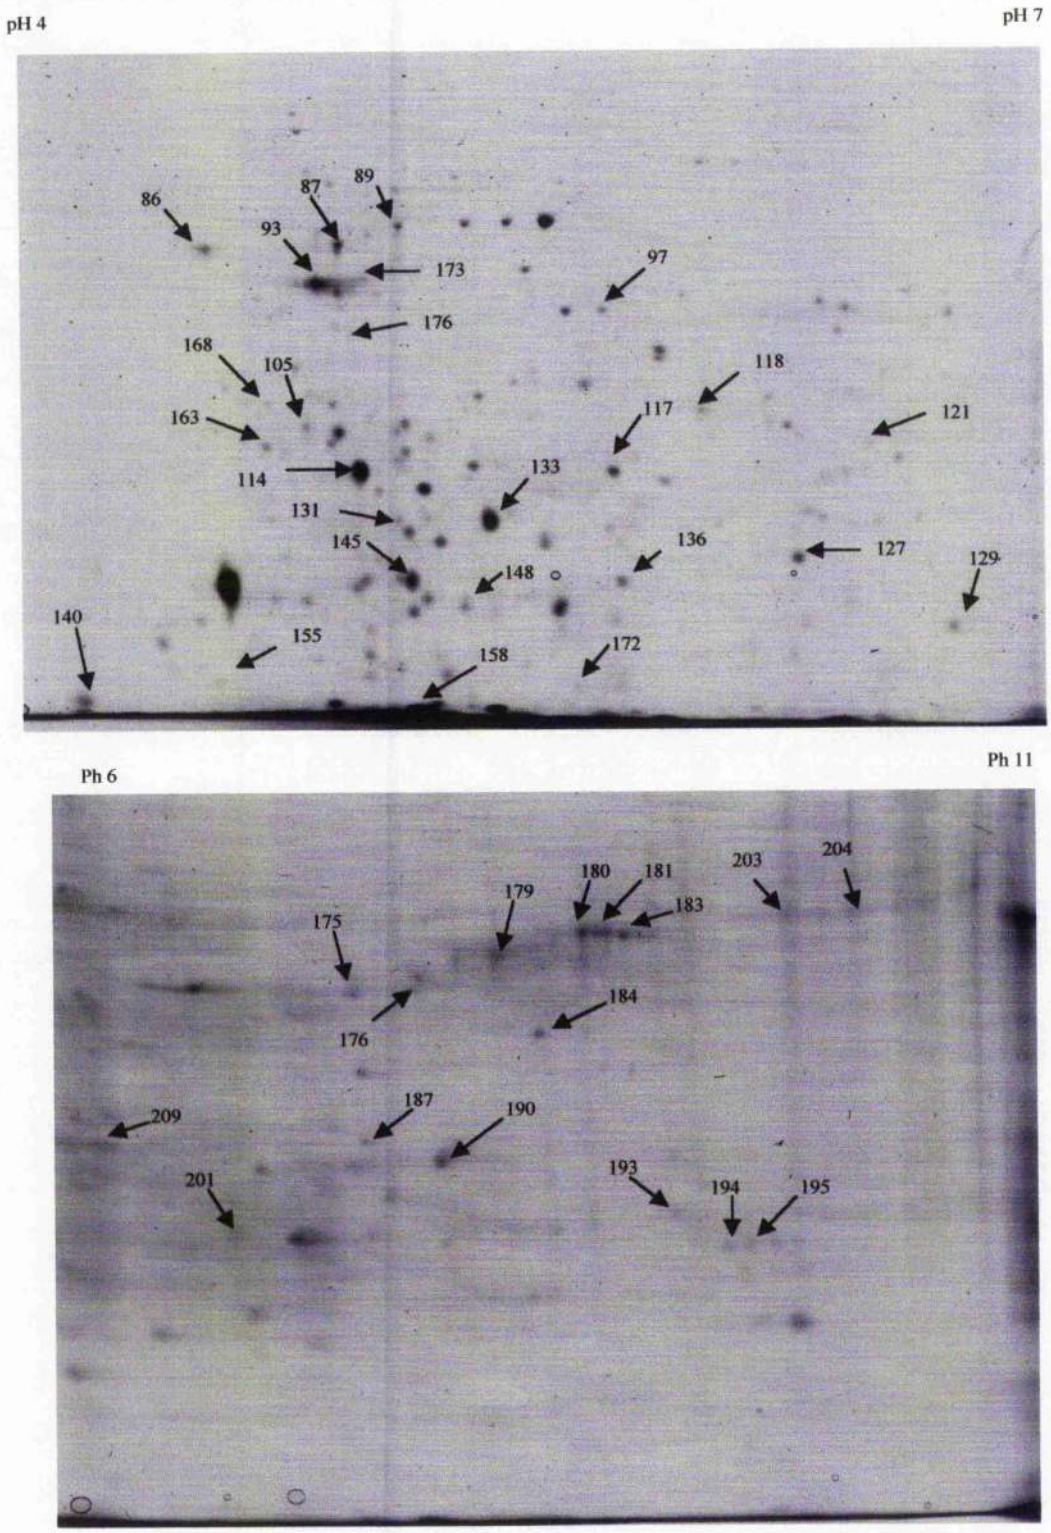

Figure 4.1: **Proteome map of *T. brucei*.** Coomassie Brilliant blue stained gel of whole cell extract from *T. brucei* line 927 separated by 2DE on pH 4-7 and pH 6-11. The proteins from which peptide mass fingerprints were generated and an identification was obtained by searching the NCBInr database and the local *T. brucei* database are indicated by an arrow.

Table 4.2: List of protein spot identified by the MASCOT® search engine. Mass fingerprints were obtained by MALDI-TOF MS. Peptide mass fingerprint were searched against NCBInr and the local *T. brucei* database using the MASCOT® search engine. The table indicates the accuracy of the match (ppm), the score of the protein, the database score (p), the coverage of the protein by the identified peptides, and the number of peptides from the fingerprint that match on the protein. The search was last carried out on the 25/06/2003. Non-annotated ORF from the local *T. brucei* database were identified by blast against the NCBI database to homologues in other species.

The majority of proteins separated by 2DE and visualised by Coomassie staining were not identified. From all the protein spots processed, 10.13% were identified as enzymes, followed by 7.14% identified as structural proteins, 7.14% identified as elongation factors and 9.52% classified as others and comtaining the hypothetical proteins (Figure 4.2).

4.3.2 Relationship of polypeptide profile complexity to gene number in *T. brucei*

An isoform is defined in the Dictionary of Cell Biology as a protein having the same function and similar (or identical) sequence but the product of a different gene and usually tissue specific (Lackie and Dow, 1995). For the purpose of this thesis, we will limit the definition of an isoform to a protein product of one or different genes with identical DNA sequences. Consequently, any isoform observed on a 2DE will be the results of a post-translational modification by either the covalent addition of a small adduct or by proteolytic processing.

The identification of protein spots by MALDI-TOF analysis showed a large proportion of α (5 spots) and β (3 spots) tubulins on the proteome map. So far, the genome sequencing project of *T. brucei* has identified 13 α tubulin genes and 14 β tubulin genes on one homologue and 9 α tubulin genes and 10 β tubulin genes on the other homologue of chromosome 1 (Hall *et al.*, 2003). Alignment of all the sequences of α tubulin genes and β tubulin genes found in the GeneDB database has shown that all α tubulin genes are identical and all β tubulin genes are identical to each other (data not shown). Consequently the tubulins spots identified from the proteome map are isoforms. The α and β tubulins spots identified are located at very different places on the proteome map, indicating that these isoforms are possibly the results of modification by proteolytic processing.

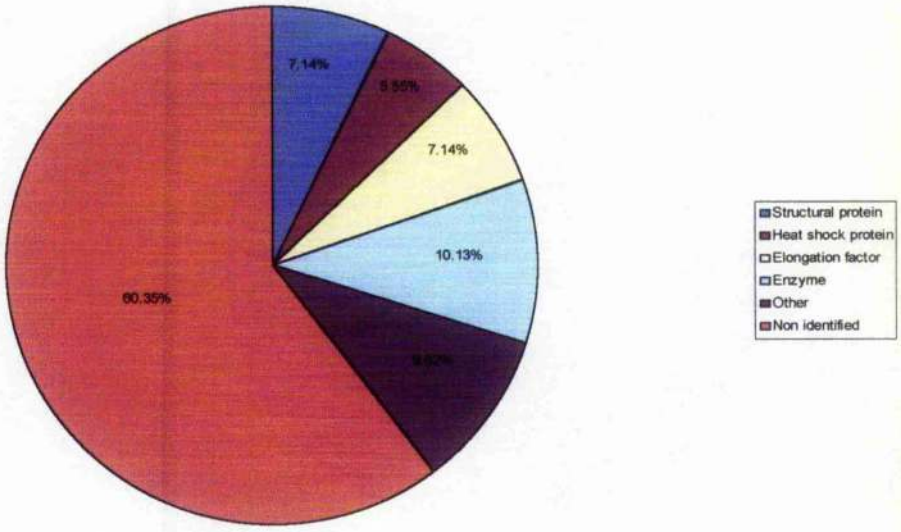

Figure 4.2: **Pie chart representation of classes of protein identified.** The class other contains the "hypothetical" proteins (4.76%) from the local *T. brucei* database for which no homologues where found in the NCBI database.

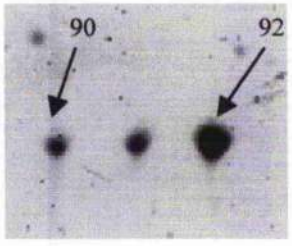

Figure 4.3: **2DE pattern of post-translationally modified proteins**. Zoom view of a part of the 2D gel (pH 4-7) showing the characteristic pattern of isoforms with similar molecular weight but slight variations in pI. Samples 90 and 92 were both identified as heat shock protein 70, transcript product of the same ORF (score: 112 and 102 respectively).

The HSP70 protein spots (spot 90 and 92) identified on the proteome map are also isoforms as they are products of the same gene. The HSP70 gene family is large but also very diverse which enabled the differentiation of the gene products by MALDI-TOF analysis, as illustrated in Figure 4.3. Protein spots 90 and 92 are located at similar apparent molecular weight but with different pI (Figure 4.4), indicating that the isoform are probably the results of post-translational modification by covalent addition of a small adduct. This suggests that the HSP70 protein is regulated at the post-transcriptional level in *T. brucei*.

In some cases however the MALDI-TOF analysis does not enable a determination of whether the protein spots identified are isoforms, or products of genes with different sequences. This was observed for spot 175, 176 and 179, all identified as elongation factor 1 α (score = 58, 72 and 67 respectively), located at similar apparent molecular weight but with differences in pI. At first glance the results from the MASCOT® search engine suggested that all three spots were transcriptional products of the same ORF (ORF 775), which had obtained the highest score. However, a closer examination of the results suggested the presence of two elongation 1 α genes (ORF 775 and ORF 774). An alignment of the transcriptional product from these two ORFs showed a difference in length between the two ORFs and 100% homology in the aligned sequences (Appendix III). The shorter ORF (ORF 775) thus obtained the best score with the MASCOT® search engine (as the percentage of coverage obtained was higher), however the mass spectrometry data obtained cannot differentiate between the two genes. Consequently, spot 175, 176 and 179 could be either post-translationally modified elongation factor 1 α or the transcripts of different genes.

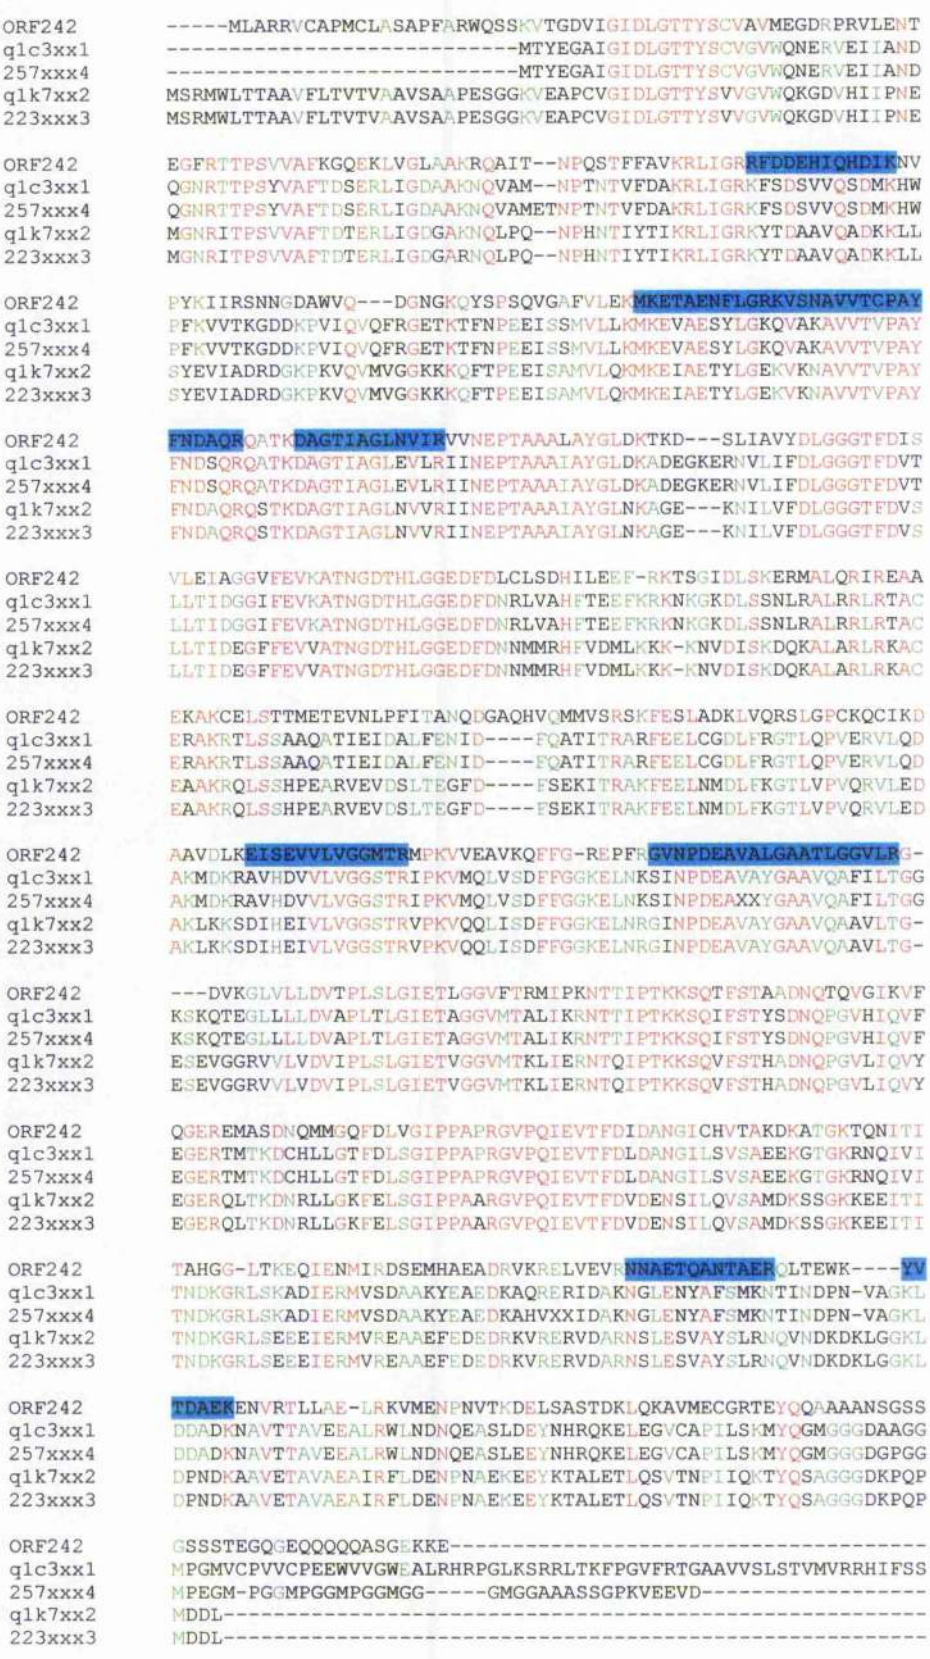

Figure 4.4: Alignment of ORFs encoding HSP70. Peptides identified by MALDI-TOF analysis of spot 90 are highlighted in blue.

4.4 Discussion

In this chapter, protein spots were digested with trypsin and 51 were identified to act as landmarks for further proteomic studies. The likelihood of obtaining identifications by peptide mass fingerprinting given the incomplete state of the *T. brucei* genome-sequencing project was determined.

There was a good correlation between spot intensity and spectrum quality, although some intense spots gave few peaks by MALDI-TOF. The proteome map revealed that 40.5% of proteins visualised by Coomassie staining can be identified using the simple peptide mass fingerprinting technique with the current state of the *T. brucei* genome database. A protein was accepted as identified only if the score was higher than the database score (p) and the accuracy under 50 ppm (chapter 3). From the 126 protein spots assessed, 10.3% were enzymes (component of the metabolic pathways), 7% were structural proteins involved in the cyto-architecture of the cell (tubulins, paraflagellar rod proteins, etc...) and 7% were elongation factors. Structural proteins are known to be highly expressed in cells, which is in accordance with the results obtained from the preliminary proteome map of *T. brucei* line 927. A significantly high proportion of identified protein spots (5.55%) were match to non-annotated, hypothetical ORFs of *T. brucei*. The identification of these genes from their protein product proves that these are real genes and that they are expressed in *T. brucei*. These ORFs were found to have no homologues in the NCBI database and so can be considered to be specific to *T. brucei*. Because of their specificity to the *T. brucei* parasite these proteins should be further analyse in view of their potential as drug targets. The sample used in this study were excised from Coomassie Brilliant blue stained gel and so there has been a unavoidable bias toward the analysis of the most highly expressed proteins.

With the available *T. brucei* database, 59% of the peptide mass fingerprints generated were not matched to a protein in the two databases searched. Closer examination of the peptide mass spectra obtained for these protein spots revealed some poor quality spectra (27 spectra) attributable to low protein concentration and so these would be unlikely to provide identification. In addition, five protein spots were lost during the in-gel trypsin digestion. Removal of the poor quality spectra and lost spots brings the percentage of non-identified proteins down to 37.6%. Inspection of the results from the MASCOT® search engine reveals that a few protein spots with good spectra were not unambiguously identified (score < database score). Closer examination of these mass spectra with the mass spectra generated for proteins located at similar molecular mass but with a slightly more acidic or basic pI revealed high similarities in the peptide masses. Examination of the results obtained with the MASCOT® search engine for these peptide mass fingerprints showed that the first scores were just under the database score necessary for unambiguous identification. In addition, the protein name and accession number associated with the highest score for these spots was the same as that for protein spots with similar molecular mass but slightly different pI. This suggested that these could be accounted for by post-translational modification. Most post-translational modifications change the masses of the modified peptides (Table 4.3). Modified peptides would not fit the theoretical values calculated from the database entries by the MASCOT® search engine and therefore these would be eliminated from the identification.

38 good quality peptide mass fingerprints had no match in either the local *T. brucei* database or the NCBI database suggesting that the sequence of the ORFs encoding these protein spots were not available in the database, and that no close homologue of the proteins

PTM type	Δ Mass (Da)	Function and notes
Phosphorylation	+ 80	Reversible, activation/inactivation of enzyme activity, modulation of molecular interactions, signaling
Acetylation	+ 42	Protein stability, protection of N terminus. Regulation of protein-DNA interactions (histones)
Methylation	+ 14	Regulation of gene expression
Glycosylation:		
N-linked	>800	Excreted proteins, cell-cell recognition/signalling
O-linked	203, >800	Reversible, regulatory functions
Hydroxyproline	+ 16	Protein stability and protein-ligand interactions
Sulfation	+ 80	Modulator of protein-protein and receptor-ligand interactions
Pyroglutamic acid	-17	Protein stability, blocked N terminus
Ubiquitination	>1,000	Destruction signal.

Table 4.3: Post-translational modifications and mass shift. Reproduced from http://www.abrf.org/index.cfm/dm.home

occur in the sequenced genome of other organisms. These spots are likely to be identified when the whole annotated genome sequence of *T. brucei* becomes available. The 59% of unidentified protein spots can be explained by a combination of some poor quality spectra (21.4%), some heavy post-translational modifications (3%) and an incomplete *T. brucei* genome sequence (34.6%).

A possible explanation for the acquisition of poor mass spectra lies in the limitations of the MALDI-TOF MS. Examination of peptide mass spectra generated by MALDI-TOF on 100 proteins from *Mycobacteria* species showed that peak intensities of arginine containing peptides were significantly higher than those of lysine peptides (Krause *et al.*, 1999). The intensity of some of the lysine peptides can be so low that these peptides cannot be separated from background noise in the peptide mass fingerprint. This characteristic of peptide mass spectrum generated by MALDI-TOF limits the sequence coverage obtainable by PMF analysis, and consequently the score given to a protein spot.

PMF has been used extensively in proteomic studies to identify proteins separated by means of 2DE. Peptide mass analysis by MALDI-TOF was shown to combine simplicity with high throughput which made it an ideal first step to large scale proteome mapping. When complete genomic sequences are available, it has been demonstrated that up to 80% of the proteins separated by 2DE and analysed by MALDI-TOF can be positively identified (Shevchenko *et al.*, 1996). However, PMF efficiency for organisms with complete genome sequenced varies enormously from as little as 33% for *Homo sapiens* to 80% for *Saccharomyces cerevisae* (Table 4.4). These large differences in PMF efficiency for organisms where the complete genome has been sequenced can be explained by the size and complexity of their genomes. The human genome (3 Gb) has been completely

Organism	**Genome sequencing project**	**Genome size**	**Predicted number of genes**	**Efficiency of PMF**	**Reference**
Saccharomyces cerevisiae	Complete	12 Mb	6,280	80%	Wildgruber *et al.*, 2002
Homo sapiens	Complete	3 Gb	924 for chromosome 21 and 22	32.6%	Ha *et al.*, 2002
Helicobacter pylori	Complete	1.66 Mb	443	50.7%	Chao *et al.*, 2001
T. brucei	Not complete	35 Mb	8,000	40.5%	

Table 4.4: Proteome mapping projects for *Saccharomyces cerevisiae*, *Homo sapiens*, *Helicobacter pylori* and *T. brucei*. The four proteomic studies were carried out by 2DE of proteins and MALDI-TOF analysis of tryptic digested proteins selected from the two dimensional gels.

sequenced but its use for proteomic studies based on protein identification by PMF is limited. This is due to the gene organisation and the mechanisms of post-transcriptional RNA processing. The average human gene contains 10 to 15 exons separated by introns. Exons only account for about 2% of the total genome and the remaining 98% constitutes introns (24%) and intergenic regions (74%). These features make it difficult to identify genes in the human genome by ORF scanning. An additional factor is the extensive occurrence of complex RNA splicing events which is a key feature of human gene transcription (Modrek and Lee, 2002; Zhang *et al.*, 2002). Analysis of chromosomes 19 and 22 showed that there are, on average, 3.2 distinct mRNA transcripts per gene, with 70% of these involving alternative splicing within the coding region (Lander *et al.*, 2001). This means that the peptides predicted directly from the ORF will not correspond to those actually translated from the alternative spliced transcripts making the identification impossible. Pseudogenes are another major problem for ORF finding in the human genome. For example, there are 80 ribosomal protein genes in the human genome but >2,000 associated pseudogenes (Zhang *et al.*, 2002). Consequently, the assignment of ORF's is particularly difficult and far from complete for the human genome. In order to have an efficient identification of peptide mass fingerprints, it is necessary to have a complete database of the total ORFs and mRNA transcripts. The need for such a "perfect" database is because of the pure statistical basis of protein identification from peptide mass data. The proteome in different tissues and cell types would then represent a sub-set of this database. However, the importance of PMF should not be under estimated as, where identification is obtained, it provides much needed confirmation that ORFs are expressed.

In comparison, the yeast genome is far simpler than the human genome. *S. cerevisiae* was the first eukaryote genome to be fully sequenced (12 Mb). The work was completed in

1996 and the detection of ORFs in *S. cerevisiae* started at the same time. The lower complexity of the yeast genome is mirrored by the efficiency of protein identification by PMF.

The *T. brucei* genome organization has been determined from the sequencing and annotation of chromosome I and II. This analysis showed a lack of promoters, no introns, but large probable polycistronic units. Except for the addition of the spliced leader on every transcript, splicing is a rare event in *T. brucei*. The simple organization of the *T. brucei* genome means that the annotation of the genome is relatively straightforward and a complete database of the total ORFs and mRNA transcripts should be obtainable directly from the genome. Consequently, proteins can be identified by direct comparison of PMF with theoretical PMF from transcripts predicted from the ORFs, and this is reflected in the relatively high rate of protein identification reported here.

Identification of protein spots on the proteome map showed that post-translationally modified proteins were separated by 2DE from the primary translated products (e.g. HSP70 protein spots). This is because most post-translational modification leads to changes in pI. This change in pI gives rise to a specific protein spot pattern on 2D gels. In this study 51 proteins spots were identified which corresponded to 30 different proteins. Consequently, 40% of the protein spots identified were likely to be isoforms. This might seem a high percentage, but comparison with proteome maps from various organisms available at the Expasy's web site (http://ca.expasy.org/ch2d/2d-index.html) showed this to be an average isoform value. Post-translational modification of a protein can determine its activity state, localisation, turnover, and interactions with other proteins. For example, kinase cascades are turned on and off by the reversible addition and removal of phosphate

groups. As such the determination of the post-translational modification state of a protein is extremely important. Proteomic studies using 2DE and mass spectrometry enable the separation and assessment of the level of modification of a protein. The particular modification and the site of modification can further be analysed by a variety of techniques which have been recently reviewed (Mann and Jensen, 2003; Mann *et al.*, 2002; Arbersold and Goodlett, 2001).

However it is difficult, sometimes impossible with PMF data to differentiate between post-translational modifications and transcripts from different but closely related genes in a gene family. For example, the number of α and β tubulins gene copies on chromosome I has been estimated (from mapping data) to be 13-14 in one homologue and at least 9-10 in the other, with high homology between them (Hall *et al.*, 2003). Remarkably, almost 20% of the annotated genes on chromosome I are members of closely related families (Table 4.5).

The production of a preliminary proteome map of *T. brucei* demonstrates the feasibility of proteomic studies on this parasite. The lack of a complete and accurately annotated genome and protein sequence databases accounted for 34.6% of the non-identified protein spots. In 3% of the cases the data collected by MALDI-TOF mass spectrometry was not sufficient for reliable identification of a protein, especially in cases were the 2DE pattern suggested post-translational modification of the protein. In cases of ambiguous identification by PMF, Tandem mass spectrometry can be used in analysis to generate peptide sequence information about a particular protein spot of interest.

Before embarking on a proteomic study of Cymelarsan resistance in *T. brucei*, a biological analysis of the isogenic lines to be used needs to be undertaken to determine potential variables which could affect the protein expression in each line. The characterization of the two pairs of isogenic lines is described in the next chapter.

Product description	Distribution	% homology (protein)	Number of copies
RHS	Clustered	20-99%	5
LRRP1	Clustered	93-99%	3
Unknown function	Clustered	75-95%	3
Phosphate permease	Tandem	97%	2

Chapter V

Characterisation of isogenic drug sensitive and drug resistant lines of trypanosomes

5.1 Introduction

In previous chapters, protocols for the extraction/solubilisation of proteins from *T. brucei* and their separation by 2DE were developed, a sensitive and specific search engine was selected for identification of proteins using mass spectrometry data and a preliminary analysis of the proteome of line 927 demonstrated that 40% of proteins separated by 2DE can be identified using the simple technique of PMF. These results have essentially established the main methodologies for undertaking proteomic analysis of *T. brucei* as well as defining the limitations. As discussed in the introduction, one application of proteomics is the analysis and identification of alterations associated with particular phenotypes and the main aim of the project was to apply this technology to analysing the alterations in drug resistant trypanosome lines.

Cymelarsan (Melarsamine hydrochloride) is a close analogue of Melarsoprol used in veterinary trypanosomiasis. Cymelarsan is a water-soluble trivalent agent that is very effective against *T. b. brucei, T. evansi* and *T. equiperdum* infections in camels, buffalo, goats and pigs (Payne *et al.*, 1994; Nyang'ao *et al.*, 1995) but is very unstable in solution and forms several dissociation products. The primary dissociation product, Melarsen oxide, is thought to be the active form of Cymelarsan (Berger and Fairlamb, 1994) as well as the primary metabolite of

Melarsoprol *in vivo* (Keiser *et al.*, 2000). Consequently, Cymelarsan generated resistance can be used as a model for Melarsoprol resistance in trypanosomes.

Cymelarsan resistance was generated *in vivo* in the STIB 386 and STIB 247 lines of trypanosomes by gradually increasing sub-curative doses of drug (Scott *et al.*, 1996). Comparison of EC_{50} values obtained from *in vitro* growth inhibition assays demonstrated that procyclic forms of the laboratory-generated Cymelarsan resistant lines were over 500 fold more resistant to Cymelarsan than the sensitive parental lines (Table 5.1). Preliminary characterisation of the two pairs of isogenic lines (386/386Mr, 247/247Mr) showed that the drug resistance phenotype was stable after passaging in mice in the absence of drug pressure as well as being stable after transmission through tsetse flies (Scott *et al.*, 1996). Cross-resistance between Cymelarsan and Melarsoprol was observed in bloodstream forms *in vivo* but not in procyclic forms in *in vitro* inhibition assays for both pairs of isogenic lines (Table 5.1). This apparent lack of cross-resistance was observed to be an artifact of the *in vitro* assay (Scott *et al.*, 1997). In addition, *in vitro* studies demonstrated that bloodstream forms of the Cymelarsan resistant 247 line was partially cross-resistant to two diamidine drugs, Pentamidine and Berenil (data not shown, Scott *et al.*, 1997).

The two pairs of isogenic lines (386/386Mr and 247/247Mr) have been previously analysed to determine whether they possess, transcribe and express the P2 transporter gene (*TbAT1*). Southern blot analysis demonstrated that the sensitive 386 and 247 lines both had the genes encoding P1 and P2 transporters. The Cymelarsan resistant 386 line possessed a *TbAT1* gene with the same restriction digestion pattern as the sensitive line, whereas the cluster of genes

Table 5.1: Results of *in vitro* and *in vivo* cross-resistance assays for the pairs of isogenic lines. Resistance of sensitive (386 and 247) and Cymelarsan induced drug resistant (386Mr and 247Mr) lines were tested by growth inhibition assay. Average EC_{50} values (μM) of Cymelarsan and Melarsoprol calculated from growth inhibition assays for the wild type and the selected lines. The minimal inhibitory concentration (MIC) values from *in vivo* assays corresponded to the dose required to cure mice infected with the unselected or selected lines. Data from Scott *et al.*, 1996.

coding for P1 transporter was rearranged (Dr R.Burchmore, personal communication). Northern analysis showed that bloodstream and procyclic forms of the Cymelarsan resistant 386 line do not transcribe the *TbAT1* gene, whereas the sensitive 386 line expressed it in both life cycle stages. Analysis of the Cymelarsan resistant 247 line showed that the *TbAT1* gene was completely lost (Dr R. Burchmore, personal communication). These unpublished data show that the loss of expression of the P2 transporter is associated with the Cymelarsan resistance phenotype. The expression of the Cymelarsan resistance in procyclic forms of trypanosomes, for which no P2 activity can be detected (de Koning *et al.*, 2000), strongly suggested that *TbAT1* is not the only gene responsible for conferring arsenical resistance in these lines. In addition, the level of Cymelarsan resistance conferred by knockout of *TbAT1* is much lower than the levels detected in these two pairs of isogenic lines (Matovu *et al.*, 2003), further supporting the theory of a multi-factorial mechanism of drug resistance.

In this chapter the genotypes and phenotypes of the isogenic Cymelarsan sensitive and resistant lines were assessed to characterize these lines more completely. An assessment of some of the variable, which can affect the proteome of the isogenic lines was undertaken. In addition, obvious candidates for the mechanism of Cymelarsan resistance in *T. brucei*, such as export of the drug by a P-glycoprotein and analysis of cross-resistance in regard to P2 transporter alteration were assessed.

5.2 Materials and Methods

5.2.1 Commonly used reagents

The trifluoperazine (TFP), prochlorperazine (PCP), verapamil, EDTA, SDS, Tris, Gentamycin, Berenil and Pentamidine were purchased from SIGMA. Proteinase K, agarose, FCS and SDM79 were purchased from Gibco BRL. Reagents purchased from other companies are indicated in the text.

5.2.2 *In vitro* culture of procyclic trypanosomes

Procyclic forms of the pairs of isogenic lines were grown *in vitro* in complete SDM79 as described in chapter 2.

5.2.3 DNA extraction and genotyping of the isogenic lines

The pellet from 1 ml of trypanosome procyclic culture was concentrated in an Eppendorf tube by centrifuging for 3 min at 12,000 g, and washed once using 500 µl of PSG buffer at pH 7.8. The trypanosomes were lysed in 100 µl of lysis buffer (50 mM Tris pH 8.0, 10 mM EDTA pH 8, 0.5% SDS) with addition of 3.3 µl of 20 mg/ml proteinase K and incubated at 56°C for 4 h. The tubes were then incubated for 5 min at 95°C to inactivate the proteinase K and stored at -20°C. Genotyping was undertaken by PCR amplification of three highly polymorphic minisatellite markers, CRAM, MS42 and 292, using the primers listed in Table 5.2 (MacLeod *et al.*, 1999). PCR was undertaken in 10 µl reaction volumes containing 5 pmol/ml of each primer, 1 µl of PCR Master mix (ABgene), 1 unit of Taq polymerase (ABgene), and 200-300 ng of DNA template. The PCR conditions were as follow: 28 cycles of denaturation for 50 sec at 95°C, annealing for 50 sec at 64°C and elongation for 3 min at 68°C, on a Robocycler

Primer	Sequence
CRAM G	5'- CTGCTGATGCCGTACATGATGATTTC
CRAM H	5'- AACTCCCTCCCGATCGATCACAAC
MS42 F	5'- TTGTGCGGTCGTTAACGCGCGTTCAA
MS42 W	5'- GGTGATTCATCGGCTCCCTTACCA
292 G	5'- ACACCCCCTCTCCACTTCAGATAC
292 H	5'- GCTGAACCTGTGGGCCCCTCAATTG

Table 5.2: Sequence of primers for genotyping. Sequences of the primers used to PCR amplify the three minisatellites CRAM, MS42 and 292 for genotyping the isogenic lines.

Gradient 96 (Stratagene). Agarose gels for electrophoresis of DNA were prepared as described in Sambrook *et al.* (1989). Powdered agarose (1% w/v, Seakem) was mixed with 0.5x electrophoresis buffer (0.045 M Tris-borate, 0.001 M EDTA) and ethidium bromide (1%). The DNA samples (10 µl) were mixed with the gel-loading buffer (0.25% (w/v) bromophenol blue, 30% (v/v) glycerol in water) and loaded into the wells. The samples were run in the gels at 100 V for 2 h 30 min. The gels were then examined under ultraviolet light and photographed with a Gel Imager.

5.2.4 *In vitro* growth curves of the isogenic lines

Procyclic forms of each isogenic line were grown by inoculating complete SDM79 with $5x10^5$ procyclic trypanosomes, and incubating the cultures at 25°C. Growth curves were obtained by estimating trypanosome concentrations every 24 h over a 7 day period using an Improved Neubauer haemocytometer. The experiments were carried out in triplicate. The mean trypanosome concentration was plotted against time in hours and from these growth curves, the rate of growth and population doubling time (PDT) were calculated. The rate of growth (b) over the first three days was calculated by linear regression analysis ($y = bx + c$). The mean PDTs were calculated from the growth rates using the following equation: $PDT = \ln 2/b$.

5.2.5 *In vitro* trypanocidal drug sensitivity testing

5.2.5.1 Growth inhibition assays

Four trypanocidal drugs were each used in *in vitro* drug resistance assays on procyclic forms of the pairs of isogenic lines. Cymelarsan (Rhône-Mérieux) and Berenil were dissolved in filter sterile complete SDM79 medium and Pentamidine was dissolved in 20% DMSO solution in complete SDM79 medium. Melarsoprol was available as a 3.6% solution in propylene

glycol. The drugs were serially diluted in complete SDM79 medium, to obtain concentrations ranging from 0.001 μM to 1,000 μM. In microtitre plates, 100 μl of drug was mixed with 100 μl of procyclic culture at $2x10^6$ trypanosomes/ml and incubated at 25°C. The controls consisted of 100 μl of complete SDM79 mixed with 100 μl of procyclic culture at $2x10^6$ trypanosomes/ml. Growth was assessed by counting the trypanosomes in an Improved Neubauer haemocytometer after 24 h incubation. The growth inhibition experiments were performed in triplicate, and repeated at least once. The percentage inhibition is expressed relative to the cell densities in culture growing in the absence of drug. The growth was plotted against increasing drug concentration, and the values between 10% and 90% growth were approximated to a straight line by linear regression (R^2 values varying from 0.92 to 0.97). The drug concentration which inhibited growth by 50% (EC_{50} value) was calculated from the regression equation.

5.2.5.2 Growth inhibition assays with Cymelarsan and P-glycoprotein inhibitors

Three general P-glycoprotein inhibitors, prochlorperazine (PCP), trifluoperazine (TFP) and verapamil were used in combination with Cymelarsan to assess the potential involvement of drug efflux as a mechanism of Cymelarsan resistance in procyclic forms of the pairs of isogenic lines. The P-glycoprotein inhibitors were serially diluted in complete SDM79 medium. The assay was performed in microtiter plates as shown in Table 5.3. The plates were incubated for 24 h at 25°C and concentration of trypanosome was determined using an Improved Neubauer haemocytometer. The experiments were performed in triplicate and repeated at least once.

5.2.5.3 The Alamar Blue assay

	Controls			Drug combination	
Cymelarsan: 1 μM	100 μl			100 μl	100 μl
Inhibitor of P-glycoprotein: 1 μM		100 μl		100 μl	
Inhibitor of P-glycoprotein: 10 μM			100 μl		100 μl
Trypanosomes (procyclic culture)	100 μl	100 μl	100 μl	100 μl	100 μl
SDM79	100 μl	100 μl	100 μl		

Table 5.3: Growth inhibition assays with Cymelarsan and P-glycoprotein inhibitors. The effect of P-glycoprotein inhibitors on growth inhibition assays of Cymelarsan were tested on procyclic forms of the pairs of isogenic lines.

Cymelarsan was serially diluted in complete SDM79 medium, with concentrations ranging from 0.001 μM to 1,000 μM. In microtiter plates, 100 μl of Cymelarsan solution was mixed with 100 μl of procyclic culture at $2x10^6$ trypanosomes/ml and 20 μl of the Alamar Blue dye. The control was made by replacing the Cymelarsan solution with complete SDM79. The plates were incubated for 24 h at 25°C. Measurements were taken with a LS 55 Luminescence Spectrometer (Perkin Elmer instruments) at 530 nm excitation and 590 nm emission wavelengths. Three initial concentrations of procyclic cultures ($2x10^6$, $4x10^6$ and $6x10^6$ trypanosome/ml) of the Cymelarsan sensitive and resistant lines were tested. Presence and viability of the trypanosomes in each well was confirmed by microscopic examination. Each experiment was performed in duplicate and replicated at least once.

5.3 Results

5.3.1 Genotypes of isogenic lines

All procyclic lines were genotyped using three minisatellite markers (CRAM, MS42, 292) as described previously by MacLeod *et al.* (1999). These minisatellite markers were selected as they are highly polymorphic and can differentiate between strains of *T. brucei* with a high probability. The genotypes of 386 and 386Mr lines (Figure 5.1A) and of 247 and 247Mr lines (Figure 5.1B) were each identical for the three minisatellite markers used in this study. These data demonstrated that the sensitive and resistant pairs of lines are indeed isogenic as originally described (Scott *et al.*, 1995) and no inadvertent substitution of one line for another with a different genotype has occurred. This finding contrasts with the genotyping results of RU15 line, a laboratory derived Melarsoprol resistant line made from 427 line, which had a

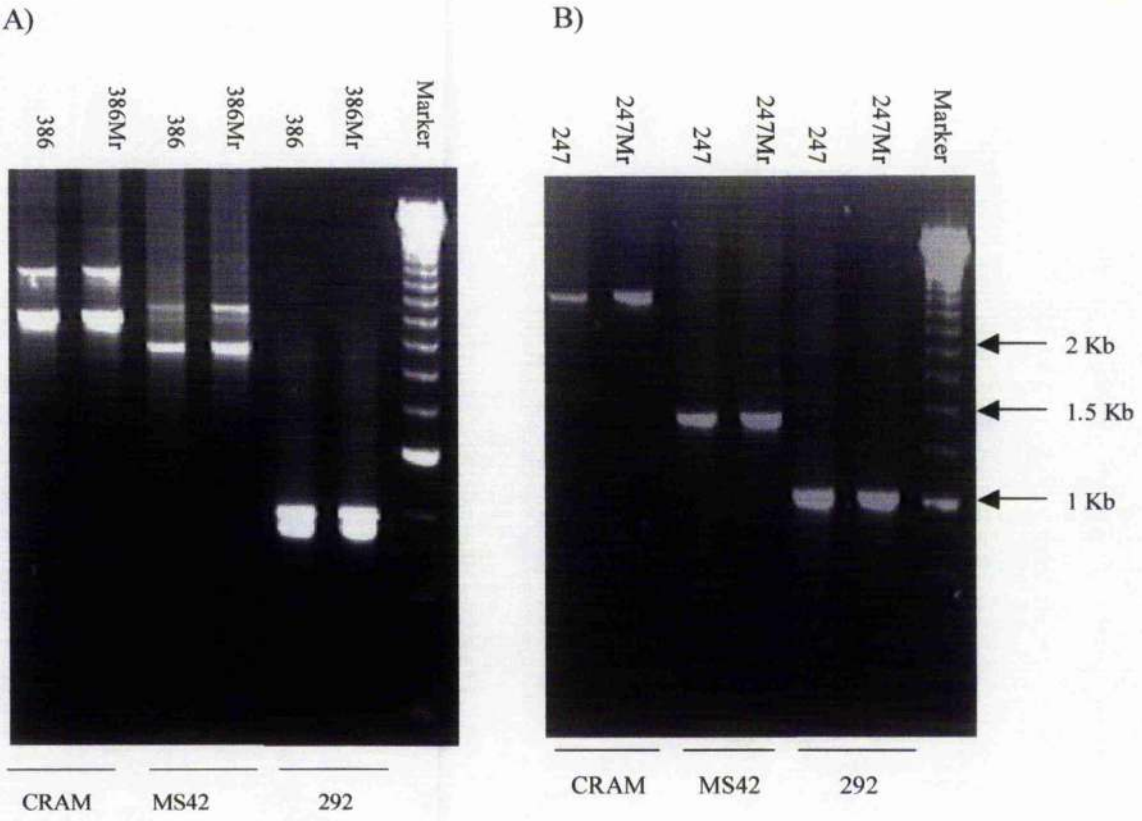

Figure 5.1: **Genotypes of the two pairs of isogenic lines**. The sizes of the PCR products correspond to the expected sizes for line 386 (2.8 Kb and 2 Kb for CRAM, 2.3 Kb and 1.8 Kb for MS42 and 1 Kb and 0.95 Kb for 292) and 247 (2.8 Kb for CRAM, 1.5 Kb for MS42 and 1.3 Kb for 292) (Dr A. MacLeod, personal communication).

different genotype from the parent line using these three minisatellite markers (Dr A. MacLeod, personal communication).

5.3.2 Growth of isogenic lines

The rates of growth of procyclic forms and the population doubling times were calculated to investigate whether selection for Cymelarsan resistance had caused a change in growth rate. The assessment of *in vitro* growth of the procyclic forms of 386 and 386Mr lines showed no noticeable difference in growth between the isogenic lines (Figure 5.2A). Both procyclic cultures reached a maximum concentration of $1.7x10^7$ trypanosomes/ml in the stationary phase. Growth rates and mean PDTs were calculated for the isogenic lines from these growth curves to assess further variability between the lines (Figure 5.2C). The growth rates were very similar (0.023 and 0.025 respectively). The *in vitro* growth curves of procyclic cultures of 247 and 247Mr isogenic lines showed no detectable differences in growth between them (Figure 5.2B). The maximum trypanosome concentration reached by these iogenic lines was $1.3x10^7$ trypanosomes/ml.

Taken together these results suggest that there are no detectable differences in growth rates between Cymelarsan sensitive and resistant lines of 386 and 247. Thus, any proteomic profile differences found between the lines are unlikely to be artefacts of differences in growth that might have arisen as a pleiotropic phenotype when the lines were originally selecting for drug resistance.

	Growth rate	Population doubling time
386	0.023	30.26 h
386Mr	0.025	27.29 h
247	0.021	32.39 h
247Mr	0.020	33.97 h

Figure 5.2: Growth curves of the two pairs of isogenic lines. Procyclic forms of isogenic lines of 386 (A) and 247 (B) were grown in SDM79 *in vitro* and the average growth rate and population doubling time (PDT) were calculated from the growth curves (C). The experiments were performed in triplicate.

5.3.3 Sensitivity and resistance to arsenicals and diamidines

In vitro growth inhibition assays of Cymelarsan sensitive and resistant lines of 386 and 247 were used to assess sensitivity/resistance of the pairs of isogenic lines to trypanocidal drugs. Two arsenical drugs (Cymelarsan and Melarsoprol) and two diamidine drugs (Pentamidine and Berenil) were tested.

The procyclic forms of 386 and 386Mr lines exhibited a dose dependent inhibition of growth by Cymelarsan. The 386Mr line was not affected to the same extent by the presence of Cymelarsan in the medium compared to the 386 sensitive parental line (Figure 5.3A). At a concentration of 1 μM Cymelarsan, the 386Mr line showed only 25% inhibition in growth whereas the 386 line showed 75% inhibition of growth. The 386 line was completely inhibited by 10 μM Cymelarsan whereas the 386Mr line was completely inhibited only by the highest concentration of Cymelarsan (1,000 μM). The minimum dose inhibiting 50% of growth (EC_{50}) was estimated to be 0.57 μM for 386 and 14.19 μM for 386Mr, showing a 24.9 fold increase in EC_{50} (Table 5.4).

The growth inhibition assays of 386 and 386Mr lines in the presence of Melarsoprol showed no detectable differences for most concentrations of Melarsoprol (Figure 5.3B). The only detectable difference was seen at a Melarsoprol concentration of 1 μM, at which the 386Mr line showed a 25% reduction in growth whereas the 386 line showed a 70% reduction in growth. Both isogenic lines of 386 exhibited a 100% inhibition of growth at a concentration of 10 μM of Melarsoprol. Comparison of the EC_{50} values of the 386 line and the 386Mr line for Melarsoprol showed less than two fold increase in resistance (Table 5.4).

Table 5.4: Average EC_{50} values (μM) from *in vitro* growth inhibition assays for the two pairs of isogenic lines. The assays were performed on procyclic forms of the pairs of isogenic lines for two arsenical drugs (Cymelarsan and Melarsoprol) and two diamidine drugs (Pentamidine and Berenil).

The phenomenon of cross-resistance between the diamidine, Berenil, and the arsenicals is commonly reported as well as cross-resistance with Pentamidine (Fairlamb *et al.*, 1992; Frommel and Balber, 1987; Pospichal *et al*, 1994). Cross-resistance between the arsenicals and the diamidinies (Berenil and Pentamidine) was assessed for procyclic forms of the pairs of isogenic lines by an *in vitro* growth inhibition assay.

Resistance of the procyclic forms of the isogenic lines of 386 to Pentamidine was tested using the *in vitro* growth inhibition assay (Figure 5.3C). The 386 and 386Mr lines showed very similar growth inhibition curves in the presence of Pentamidine. 100% growth inhibition was detected at a concentration of 1,000 μM Pentamidine for both lines. Comparison of the EC_{50} values showed a slight increase (1.56 fold) in resistance to Pentamidine (Table 5.4). Two growth inhibition assays for 386 and 386Mr lines were conducted for the diamidine drug Berenil (Figure 5.3). Berenil is a trypanostatic drug and as such might require a longer period of exposure to inhibit the growth of the trypanosomes. Consequently, concentrations of trypanosomes were calculated after 24 h (Figure 5.3D) and 48 h (Figure 5.3E) of incubation in the presence of Berenil. For both growth inhibition assays the resistance pattern of 386 and 386Mr lines were very similar. Berenil had no noticeable effect on the growth of the isogenic lines up to a concentration of 10 μM. Both lines exhibited 100% growth inhibition when incubated in 1,000 μM Berenil for either 24 h or 48 h. The EC_{50} values for the isogenic lines were compared showing that the 386 and 386Mr lines had similar sensitivity to Berenil (Table 5.4).

Growth inhibition assays were conducted *in vitro* on procyclic forms of Cymelarsan sensitive and resistant 247 lines to assess their sensitivity to two arsenical-based drugs (Cymelarsan and Melarsoprol) and two diamidine drugs (Pentamidine and Berenil).

The isogenic lines showed a dose dependent growth inhibition by Cymelarsan and 100% inhibition of growth of the 247 sensitive line was observed at a concentration of 1 μM Cymelarsan (Figure 5.4A). This concentration of Cymelarsan had no inhibitory effect on the growth of the resistant line. 100% inhibition of growth of the 247Mr line was observed at a Cymelarsan concentration of 1,000 μM. Comparison of the EC_{50} values for the isogenic lines showed a 1,247 fold increase in resistance to Cymelarsan by the resistant line (Table 5.4). Growth inhibition assays of the isogenic lines with Melarsoprol showed a slight difference between the lines at concentrations of 0.1 μM and 1 μM of Melarsoprol (Figure 5.4B). At a concentration of 10 μM of Melarsoprol both 247 and 247Mr lines exhibited 100% inhibition of growth. Comparison of the EC_{50} values obtained for Melarsoprol with the isogenic lines showed a 2.5 fold increase in resistance to Melarsoprol in the 247Mr line (Table 5.4).

Procyclic forms of the 247 and 247Mr lines exhibited similar growth inhibition patterns in increasing concentration of Pentamidine (Figure 5.4C). No effect on the growth of the isogenic lines was noticeable up to a concentration of 10 μM Pentamidine. At the highest concentration of Pentamidine tested (1,000 μM), 93% of growth was inhibited. The 247 showed less than a two fold increase in resistance to Pentamidine when compared with the 247Mr line (Table 5.4). The growth inhibition assays of 247 and 247Mr lines in the diamidine drug Berenil showed no detectable difference in growth (Figure 5.4D). At a concentration of

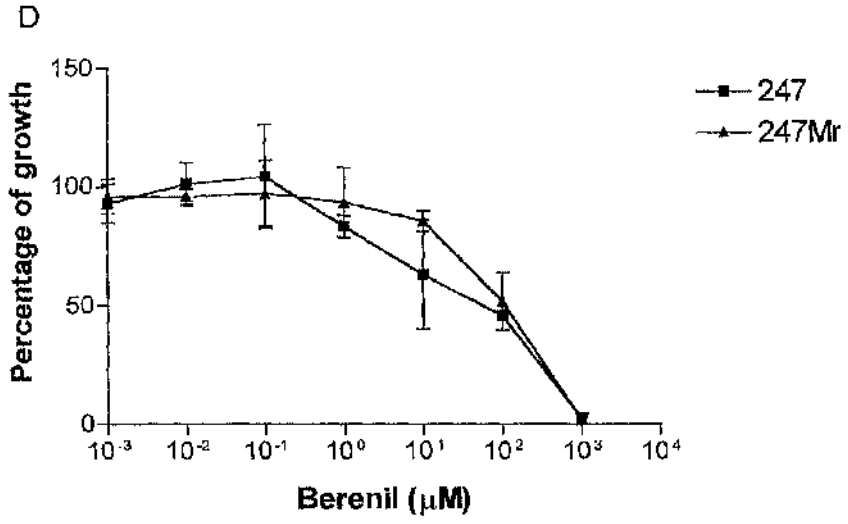

Figure 5.4: *In vitro* growth inhibition assay in arsenical and diamidine drugs for the isogenic 247 lines. Procyclic forms of sensitive and Cymelarsan resistant 247 lines were grown in SDM79 in the presence of the trypanocidal drugs Cymelarsan (A), Melarsoprol (B), Pentamidine (C), Berenil (D). The lowest concentration corresponds to the control in the absence of drug. The error bars represent the mean +/- SEM, n = 6.

1,000 μM Berenil both trypanosomes lines exhibited a 100% inhibition of growth. The EC_{50} values were calculated for both isogenic lines and a comparison of these showed a 2.2 fold increased in sensitivity to Berenil by the 247Mr line (Table 5.4).

These results confirmed that the procyclic forms of the Cymelarsan resistant lines were resistant to Cymelarsan as compared to the sensitive parents, as originally described (Scott *et al.*, 1996). Taken together these results suggest that in *in vitro* growth inhibition assays the procyclic forms of the pairs of isogenics lines had no cross-resistance between Melarsoprol and Cymelarsan, and no cross-resistance to the diamidine drugs in either of the pairs of isogenic lines.

5.3.4 The effect of P-glycoprotein inhibitors on Cymelarsan resistance

Recently, two genes encoding P-glycoproteins have been identified in the *T. brucei* genome (Shahi *et al.*, 2002). Over-expression of one of these genes, the *TbMRPA* gene, was linked to a 10 fold increase in Melarsoprol resistance (Shahi *et al.*, 2002). This report raised the question as to whether the resistance of the drug selected lines in this study could arise from a change in expression of either of these P-glycoprotein genes. To test this hypothesis, an investigation of growth inhibition by Cymelarsan in the presence of three candidate inhibitors of P-glycoprotein was carried out.

Three general P-glycoprotein inhibitors (verapamil, PCP and TFP) were used in combination with Cymelarsan in *in vitro* assays to assess Cymelarsan efflux as a potential mechanism for drug resistance in procyclic forms of the two pairs of isogenic lines. Verapamil at concentrations of 1 μM or 10 μM had no growth inhibitory effect on any lines (Figure 5.5A

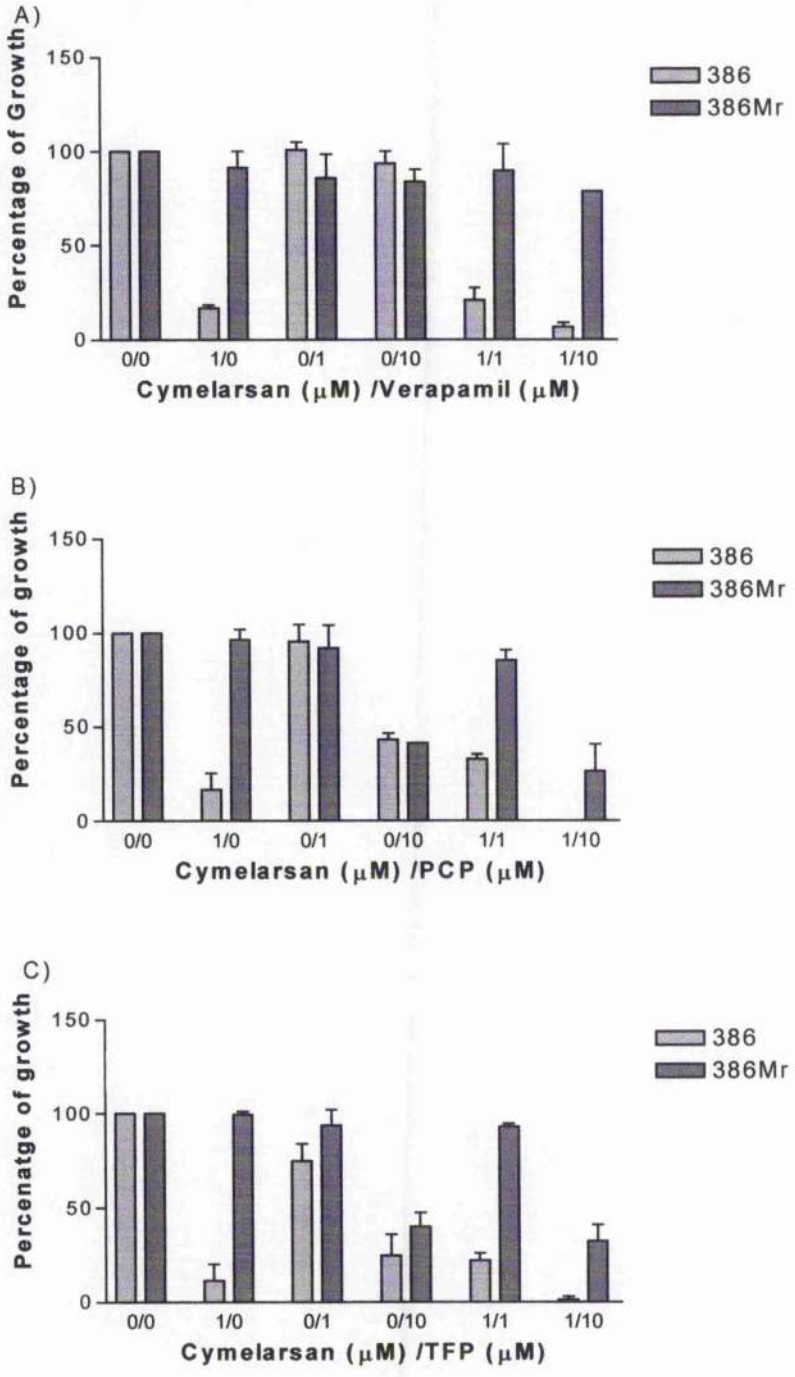

Figure 5.5: ***In vitro*** **growth inhibition assays of isogenic 386 lines in the presence of Cymelarsan and P-glycoprotein inhibitors.** The assays were performed on procyclic forms. Three general P-glycoprotein inhibitors (verapamil (A), PCP (B) and TFP(C)) were tested. The error bars represent the mean +/- SEM, n = 6.

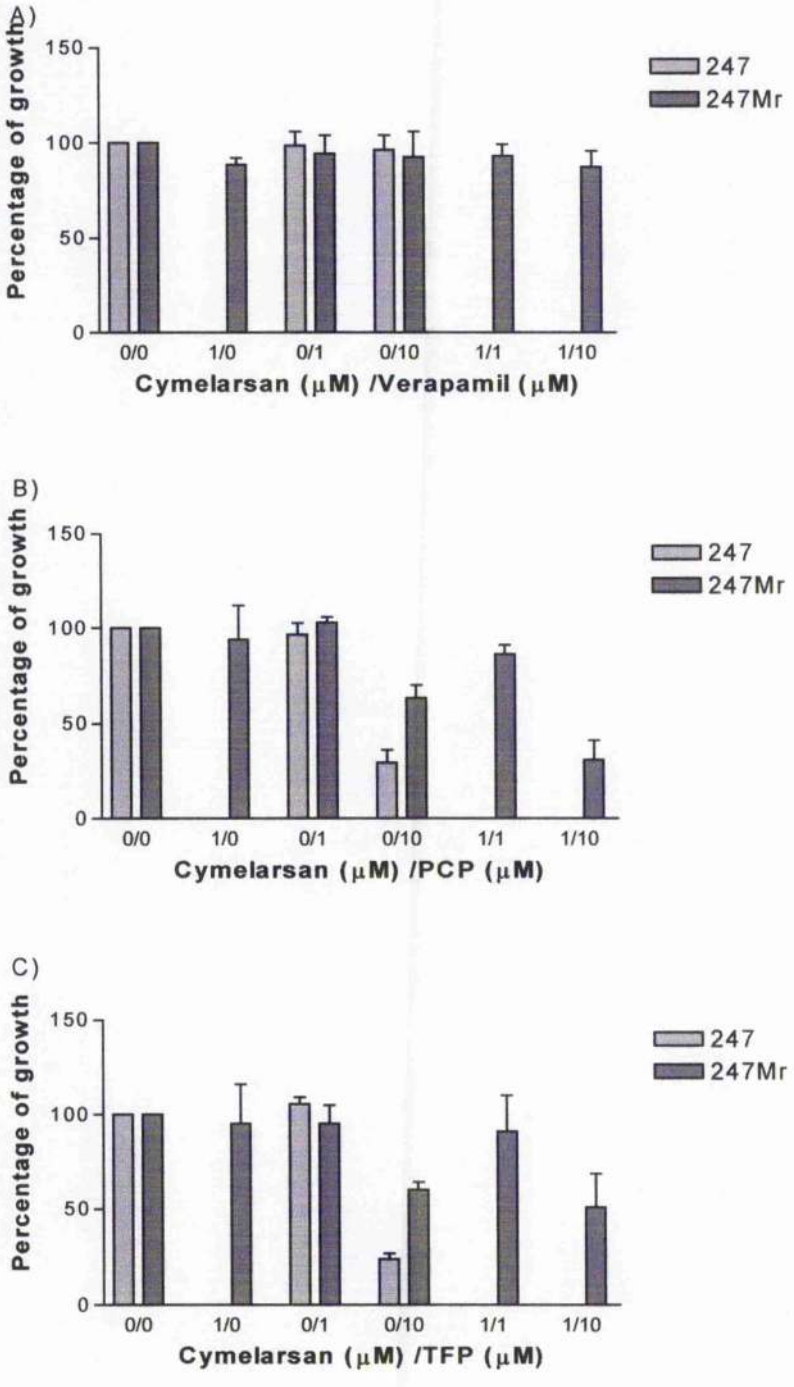

Figure 5.6: ***In vitro*** **growth inhibition assay of isogenic 247 lines in the presence of Cymelarsan and P-glycoprotein inhibitors**. The assays were performed on procyclic forms. Three general P-glycoprotein inhibitors (verapamil (A), PCP (B) and TFP(C)) were tested. The error bars represent the mean +/- SEM, n = 6.

and 5.6A). The addition of verapamil did not prevent the inhibition of growth produced by the presence of the arsenical in the medium (Figure 5.5A and 5.6A). These results were observed for all four lines tested. Both PCP and TFP were shown to be toxic to procyclic forms of all lines at a concentration of 10 μM, but had no effect on growth at 1 μM. Comparison of the growth of trypanosomes exposed to 1 μM of TCP or PCP in the presence of either 0 μM or 1 μM of Cymelarsan demonstrated that these P-glycoprotein inhibitors had no noticeable effect on the resistance to Cymelarsan (Figures 5.5B, 5.5C, 5.6B and 5.6C).

These results suggest that efflux of Cymelarsan by an over-expressed or altered P-glycoprotein in the Cymelarsan resistant 386 and 247 lines was not involved in the mechanism of Cymelarsan resistance in procyclic forms.

5.3.5 Drug sensitivity testing using the Alamar Blue assay

The use of the Alamar Blue dye is based on the ability of cellular enzymes to reduce the non-fluorescent blue dye to a pink fluorescent compound, allowing detection of cell growth by spectrofluorometry and spectrometry. The Alamar Blue assay was recently developed as an *in vitro* assay to test for drug sensitivity of procyclic trypanosomes in culture (Räz *et al.*, 1997). This assay was shown to be simple, reproducible and economical.

The Alamar Blue assay was used to assess the sensitivity or resistance of the procyclic forms of the pairs of isogenic lines in *in vitro* culture as an alternative to the growth inhibition assay. The assay was first performed on procyclic cultures in the absence of drug and demonstrated that the level of reduced Alamar Blue dye produced by Cymelarsan resistant lines was lower than the level produced by sensitive lines (Figure 5.7). The assay was then performed in

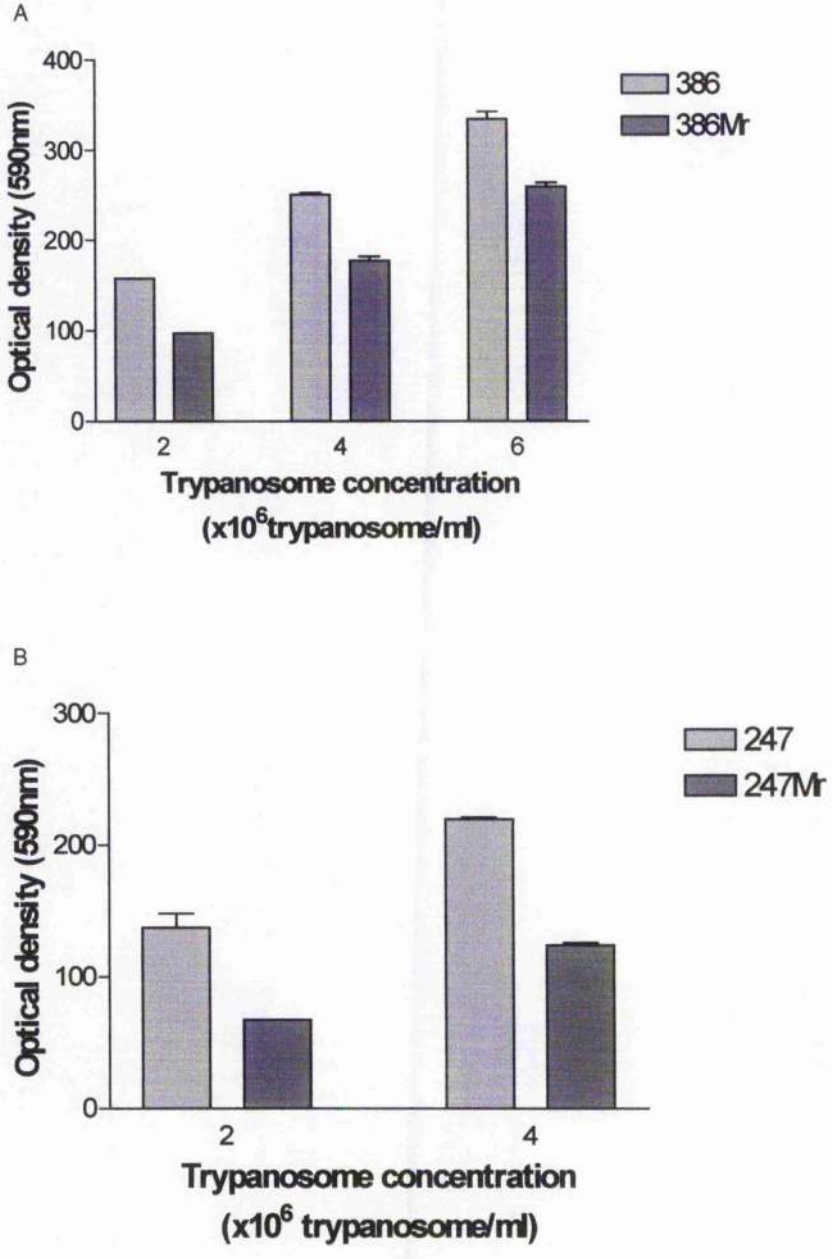

Figure 5.7: **Alamar Blue assays on the pairs of isogenic lines in the absence of drug.** *In vitro* reduction of the Alamar blue dye by procyclic forms of isogenic lines of 386 (A) and 247 (B) in SDM79. The error bars represent the mean +/- SEM, n = 4.

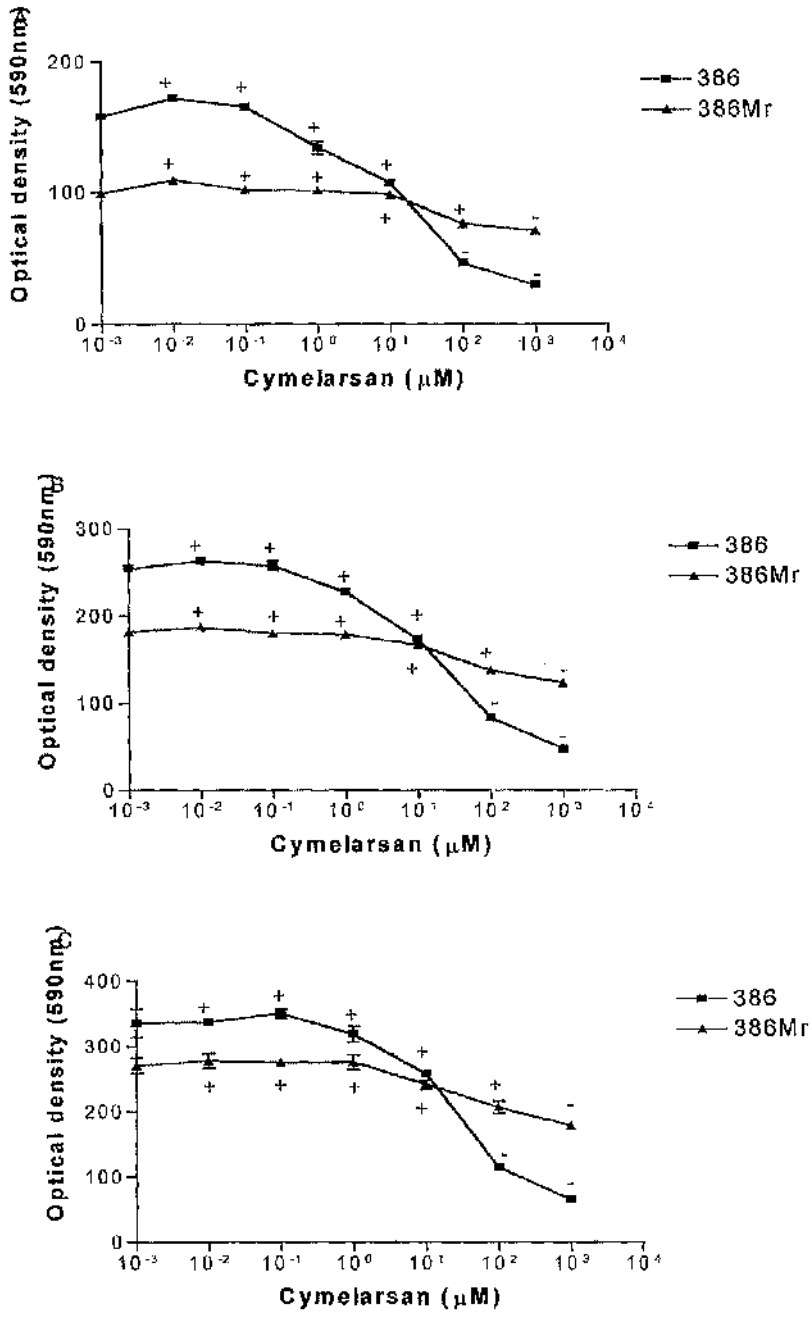

Figure 5.8: Alamar Blue assay on the isogenic 386 lines in the presence of Cymelarsan. Three concentrations of procyclic cultures were tested: $2x10^6$ (A), $4x10^6$ (B), $6x10^6$ (C) trypanosomes/ml. The status of the procyclic culture is indicated as alive (+) or dead (-) as assessed by microscopy. The lowest concentration corresponds to the control in the absence of drug. The error bars represent the mean +/- SEM, n = 4.

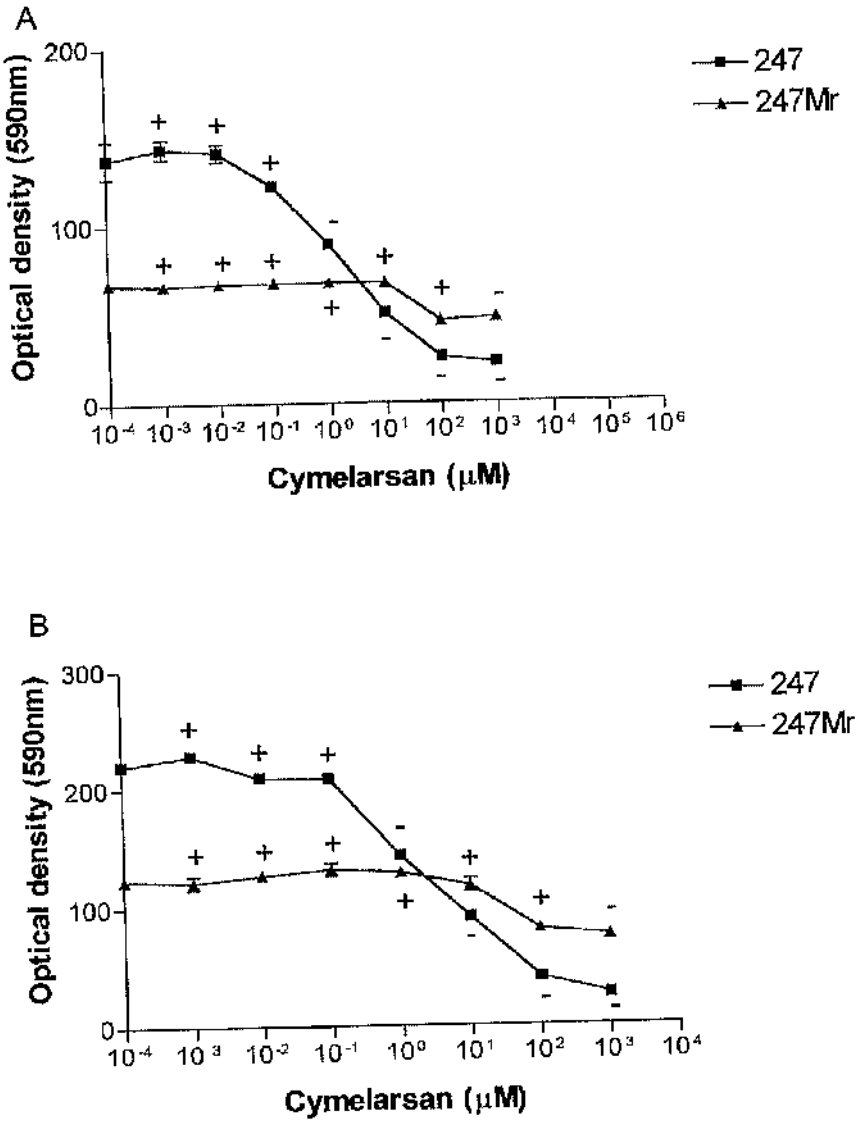

Figure 5.9: Alamar Blue assay on the isogenic 247 lines in the presence of Cymelarsan. Three concentrations of procyclic cultures were tested: $2x10^6$ (A), $4x10^6$ (B) trypanosomes/ml. The status of the procyclic culture is indicated as alive (+) or dead (-) as assessed by microscopy. The lowest concentration corresponds to the control in the absence of drug. The error bars represent the mean +/- SEM, n = 4.

increasing concentration of Cymelarsan. The 386 and 247 lines both exhibited a dose-dependent killing of the trypanosomes (Figures 5.8 and 5.9). However, the 386Mr and 247Mr lines showed very little dose-dependent killing of the trypanosomes. Microscopic examination of the culture confirmed the presence and viability of the Cymelarsan resistant lines in the culture medium for concentration ranging from 10^{-3} to 10^{2} µM of Cymelarsan.

These results suggest that the mechanism of reduction of the Alamar Blue dye has been modified during the selection for Cymelarsan resistance in *T. brucei* lines of 386 and 247. This unexpected result is investigated further in chapter 8.

5.4 Discussion

The main mechanism of arsenical resistance in trypanosomes has long been thought to be due to an alteration in uptake of the drugs mediated by the P2 transporter. However, no activity of the P2 transporter has been found in procyclic stages of trypanosomes (de Koning *et al.*, 2000). A recent study on field isolates from Uganda has demonstrated the presence of un-mutated *TbAT1* gene in 50% of the relapsed patients (Matovu *et al.*, 2001). In addition, the knockout of the *TbAT1* gene only conferred a three fold resistance to Melarsoprol (Matovu *et al.*, 2003), which is below the reported resistance observed in *in vivo* experiment in the two pairs of isogenic lines used in this study (MIC > 40 mg/Kg; Table 5.1). Consequently, the mechanism of resistance to the arsenicals drugs appears to be multi-factorial and necessitates to be investigated.

The procyclic forms of the laboratory-generated Cymelarsan resistant lines differ from the sensitive lines in their ability to survive in high concentration of Cymelarsan. Comparison of EC_{50} values calculated from growth inhibition assays evaluated the resistance as 25 fold in the 386 lines and 1,247 fold in the 247 lines. These values are different from the resistance levels described previously for procyclic forms of these lines which were a 500 fold increase in resistance for both pairs of isogenic lines (Scott *et al.*, 1996). The difference in resistance level could be explained by the use of a different assay to evaluate the EC_{50} values.

The use of growth inhibition assays with Melarsoprol, Pentamidine and Berenil demonstrated the absence of cross-resistance between Cymelarsan, Melarsoprol and the diamidines drugs. All four drugs are known to enter the trypanosomes via a nucleoside transporter, the P2 transporter, in bloodstream forms (de Koning, 2001). However, the P2 tranporter was shown to be a minor entry route for Pentamidine which can also be mediated by HAPT1 and LAT1 (de Koning, 2001), potentially explaining the lack of cross-resistance observed between Cymelarsan and Pentamidine in this study.

The lack of cross-resistance with Melarsoprol was expected in the assay of procyclics as Melarsoprol itself is not thought to enter the trypanosome via the P2 transporter despite the fact that this molecule possesses the recognition site for the P2 transporter (de Koning, 2001). Instead, Melarsoprol is thought to enter the trypanosomes via passive diffusion. In order to enter via the P2 transporter, Melarsoprol first requires to be metabolised into Melarsen oxide and this only happens *in vivo* (Keiser *et al.*, 2000). This explains why cross-resistance was

observed in the bloodstream forms of the two pairs of isogenic lines between Cymelarsan and Melarsoprol and not in procyclic forms (Scott *et al.*, 1996).

Two genes encoding P-glycoprotein were recently discovered in the genome sequencing project of *T. brucei* (Shahi *et al.*, 2002) with good homologies to both *Leishmania* and *T. cruzi* P-glycoprotein genes (Figure 5.10). The over-expression of one of the genes, *TbMRPA*, in line 927 was reported to confer a 10 fold increase in Melarsoprol resistance while over-expression of the second gene (*TbMRPE*) was associated with resistance to Suramin. From these data one hypothesis was that over-expression of the *TbMRPA* gene could account for some or all of the resistance observed in the lines studied here. Inhibition of P-glycoproteins using specific inhibitors demonstrated that an over-expression or alteration of this gene was not associated with Cymelarsan resistance in *T. brucei*.

The Alamar Blue assay has been recently shown to enable the determination of sensitivity of *T. b. gambiense* and *T. b. rhodesiense* to Melarsoprol, DFMO, Pentamidine and Suramin (Räz *et al.*, 1997). The assay is based on the reduction of the Alamar Blue dye, by intracellular enzymes, which correlates with cell growth and metabolic activity in the presence/absence of drug. The use of the *in vitro* Alamar Blue assay on each pair of isogenic lines in the absence of drug has demonstrated the reduced fluorescence obtained from the dye by the Cymelarsan resistant lines. In addition, the expected dose-dependent response to Cymelarsan, corresponding to a loss of viability, was only observed for the sensitive lines. No change in the fluorescence level due to the reduction of Alamar Blue was observed for the resistant lines with increasing level of Cymelarsan and loss of viability. The alteration in the fluorescence

level produced by the Cymelarsan resistant line could be due to a defect in the activity of the intracellular enzymes or an alteration in the transport/export of the Alamar Blue dye. The analysis of these two hypothesc has been undertaken and the results are presented in chapter 8.

The Cymelarsan resistance observed in the two pairs of isogenic lines was not associated with either a lack of expression of the *TbAT1* gene or over-expression or alteration of a P-glycoprotein. Consequently, the resistance mechanism in the procyclic forms of these lines does not follow the conventional pattern described so far in the literature. Other genes/proteins must be involved in the Cymelarsan resistance which have so far not been identified.

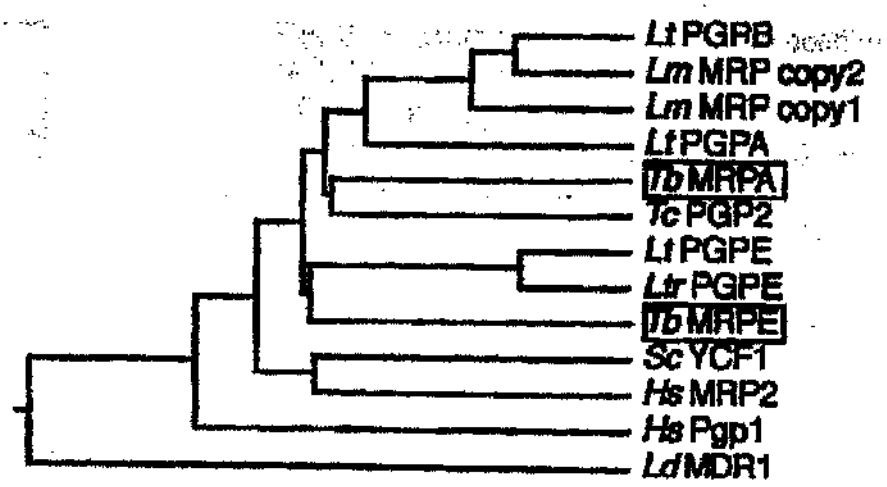

Figure 5.10: Evolutionary tree showing selected multidrug resistant proteins (MRP) and P-glycoproteins (Pgp). Species are *Homo sapiens* (Hs), *Leishmania tarenolae* (Lt), *Leishmania tropica* (Ltr), *Leishmania donovani* (Ld), *Leishmania major* (Lm), *Saccharomyces cerevisiae* (Sc), *Trypanosoma brucei* (Tb) and *Trypanosoma cruzi* (Tc). The two genes encoding MRPs from *T. brucei* are boxed. (Reproduced from Shahi *et al*, 2002)

Chapter VI

A proteomic approach to study Cymelarsan resistance in *T. brucei* line 386

6.1 Introduction

Analysis of the isogenic sensitive and resistant lines of 386 demonstrated that both procyclic and bloodstream forms exhibited the Cymelarsan resistance phenotype (Scott *et al.*, 1996). The cross-resistance analysis in procyclic forms of the 386 lines ruled out the involvement of the P2 transporter in the mechanism of arsenical resistance (chapter 5). In addition, the inhibition of P-glycoproteins had no effect on the resistance phenotype of the 386Mr line, arguing against the hypothesis that increased efflux of the drug by an over-expressed P-glycoprotein could explain the Cymelarsan resistance. With the increase number of reported cases of Melarsoprol refractory parasites in the field (Stanghellini and Josenando, 2001; Legros *et al.*, 1999; Brun *et al.*, 2001; Matovu *et al.*, 2001) it is imperative to determine the genes/proteins involved in the mechanism of arsenical resistance. The well-characterised laboratory derived isogenic lines of 386 were used as a model to determine the mechanisms of drug resistance.

There are a number of approaches to identify the genes that determine resistance to arsenical drugs in *T. brucei*. These include genetic analysis/positional cloning (Tait *et al.*, 2002), biochemical analysis (Fairlamb, 2002), cloning and functional analysis of candidate genes (Mäser *et al.*, 1999) and phenotypic analysis of isogenic parasites lines which are resistant or sensitive to the drug. The particular approach taken depends to a large extent on the hypotheses as to the mechanism of drug resistance. In the case of laboratory-selected lines, it is likely that multiple mechanisms occur to confer the final resistance

phenotype. In principle, a range of mechanisms could be put forward that include point mutations or deletions in genes involved in drug transport, in the drug target or involved in drug degradation, as well as alterations in the level of expression of any of these genes. The advantages of using either a proteomic or microarray approach in this context are that, in principle, all the possible mechanisms could be identified, although microarray analysis will only identify alterations in gene expression at the transcriptional level.

A proteomic approach, assessing the level of protein expression in a pair of isogenic lines was preferred to a micro-array approach. Measured mRNA levels are often implicitly or explicitly extrapolated to indicate levels of activity of the corresponding protein in cell. Even a bacterium with a small genome such as *Mycoplasma genitalium* had 24% more proteins expressed than the number predicted on a simple one gene, one protein system (Wasinger *et al.*, 2000). Similarly, a correlation coefficient of 0.48 was obtained between the mRNA and protein abundance determined by 2DE and gel imaging of human tissues (Anderson and Seilhamer, 1997). This correlation coefficient was confirmed using techniques such as immunoaffinity-HPLC and Northern analysis (Anderson *et al.*, 1998). These proteomic analyses illustrated the strength of 2DE analysis over micro-array technology. The low correlation coefficient obtained is probably due to the fact that the rate of degradation of individual mRNAs and protein differ. Proteins are very often the target of drugs and so measuring proteins directly gives a more accurate picture of the biology of a cell under various conditions. Proteome profiles can be scanned and quantitated to search for protein differences such as changes in levels of pre-existing proteins, induction of new products and alterations in amino acid sequence. 2DE is a relatively simple and reproducible technique. Proteome analysis provides data that are of

critical importance for the description of the state of a biological system and that are not readily apparent from the sequence and the level of expression of mRNA transcripts.

While the number of global proteomic expression profiling studies with pathogens such as bacteria and viruses are numerous, the application of these methodologies to protozoan parasites has lagged behind. This can be attributed to a number of causes, one of these is that protozoan parasites tend to be difficult to culture and manipulate *in vitro*, making it difficult to obtain enough pure material for proteomic analysis. However, procyclic forms of *T. brucei* can be cultured relatively easily *in vitro* and a reproducible solubilisation protocol for 2DE analysis of proteins from trypanosomes has been developed in this study (chapter 2). This enables a proteomic expression profiling study to be carried out and a comparative analysis made between Cymelarsan sensitive and resistant isogenic lines.

Differentially expressed protein spots can be analysed by mass spectrometry methods enabling protein identification. In the case of *T. brucei*, approximately 40% of protein spots are predicted to be identifiable using the simple technique of PMF with the current level of annotation of the *T. brucei* genome (chapter 4). For protein spots which cannot unambiguously be identified by PMF, Tandem MS can be used to generate tryptic peptide sequence information that would either confirm tentative MALDI-TOF identification or more readily identify the gene if it is present in the database. In order to analyse the basis of Cymelarsan resistance and identify pathways involved in the response to drug treatment, the strategy illustrated in Figure 6.1 was used.

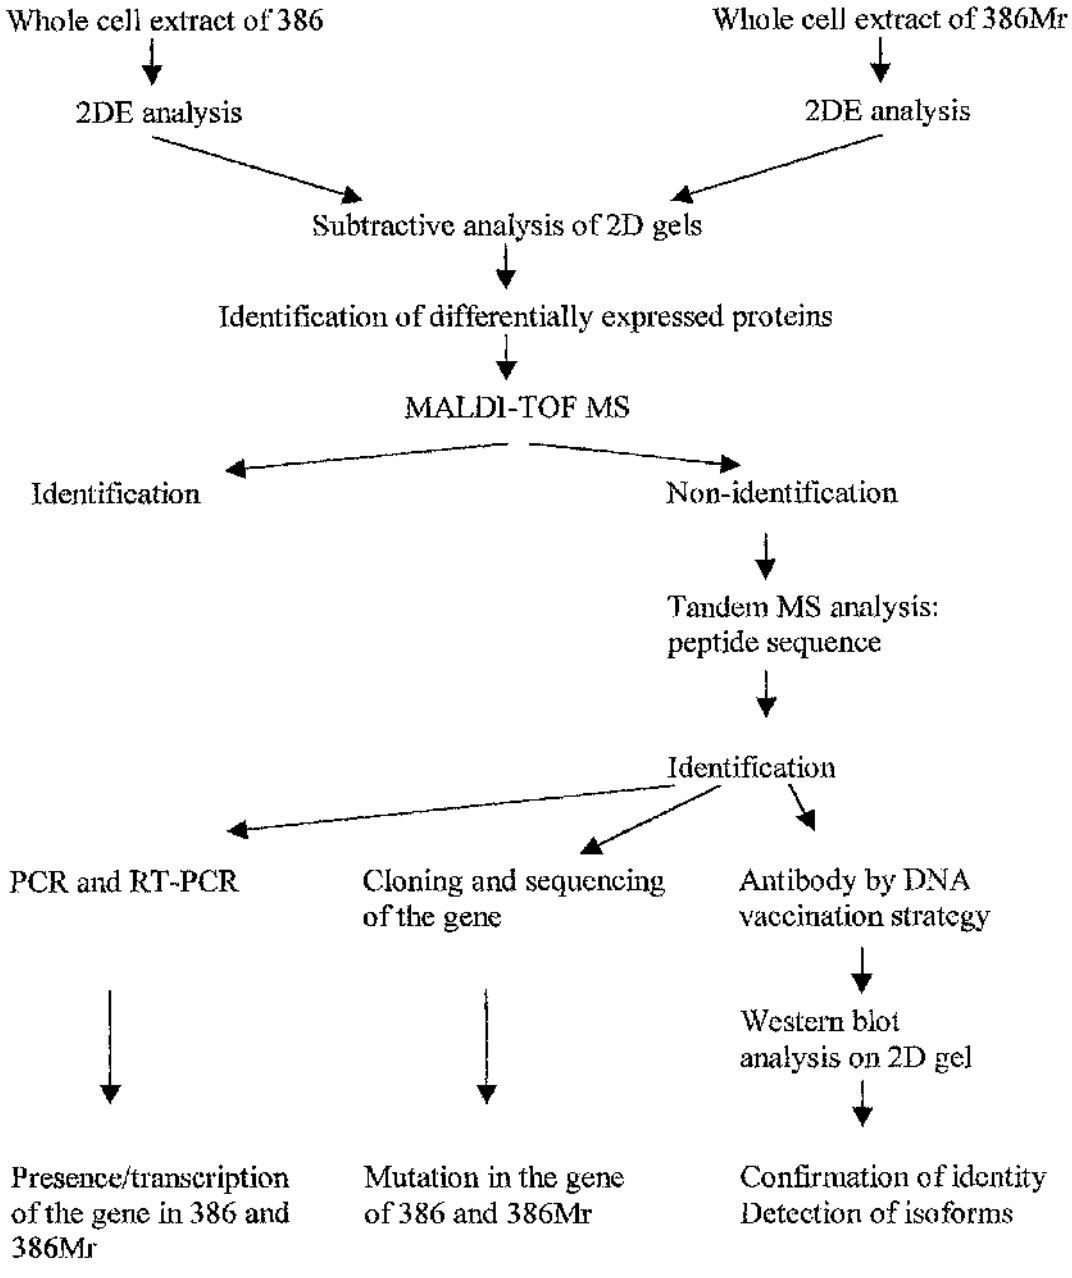

Figure 6.1: Schematic representation of strategies employed to determine protein associated with arsenical resistance in isogenic 386 lines. Two mass spectrometry approaches were used to increase the likelihood of identification of the differentially expressed protein. Mass spectrometry data were searched against the NCBInr and the local *T. brucei* database using the MASCOT® search engine. The corresponding genes were then further analysed to assess their presence/absence, transcription and mutations in the lines.

In this chapter, proteomic techniques were used to compare whole soluble protein expression patterns between Cymelarsan sensitive and resistant 386 lines and so detect variation in protein expression associated with arsenical resistance. In addition, these protein expression patterns were also compared with those of the Cymelarsan resistant 386 line growing in 1 μM Cymelarsan to determine whether some protein expressions were induced in the presence of Cymelarsan. Differentially expressed protein spots were identified using mass spectrometry techniques and the corresponding genes identified. These genes were further analysed to define the alterations associated with arsenical resistance.

6.2 Materials and Methods

6.2.1 Commonly used reagents

The QIAGEN plasmid minikit, QIAquick gel extraction kit, EndoFree plasmid Maxi kit and Ni-NTA agarose were all purchased from Qiagen. The competent cells (Top 10, DH5α and BL21AI *E. coli* cells), Rnase Out, Sperscript RT, L-arabinose and the TOPO vector were purchased from Invitrogen. The enzymes, EcoRI, HindIII, BamHI and BsaJI were purchased from New England BioLab. The antibiotics (Ampicillin and Kanamycin), X-gal, Chloroform, Isopropanol, DEPC, formaldehyde and formamide were purchased from SIGMA. Trizol, pDONR211 plasmid and pDEST17 vector were purchased from GIBCO BRL®. Custom PCR MasterMix and the Taq polymerase were purchased from ABgene. Microspin TM S 200HR, Hybond-N nylon membrane, X-ray films, pre-cast 12% polyacrylamide 24 cm gels and the DALT II vertical tank were purchased from Amersham Biosciences. Oligonucleotides were synthesised by MWG Biotech.

6.2.2 *In vitro* culture of procyclic trypanosomes

The *in vitro* procyclic cultures of Cymelarsan sensitive and resistant lines of 386 in SDM79 were performed as described in chapter 2. In addition, the Cymelarsan resistant 386 line was grown in complete SDM79 medium supplemented with 1 µM Cymelarsan solution diluted in complete SDM79 medium.

6.2.3 Protein extraction, 2DE and mass spectrometry techniques

6.2.3.1 Protein extraction and 2DE

Proteins extraction from the procyclic cultures was performed as described in chapter 2 (protocol P2) except that 470 µl of solubilisation buffer was used instead of 350 µl. 24 cm strips were used in this study to separate the proteins in the IEF. Rehydration of the strip was performed using 470 µl of protein extract and separation by IEF was performed as described in chapter 2, except that the last separation step at 8,000 V was increased to 8 h. The second dimension of the 2DE was run with 24 cm, 12% polyacrylamide pre-cast gels in a DALT II vertical tank according to the manufacturer's instructions.

6.2.3.2 MALDI-TOF and Tandem MS

Trypsin digestion of protein spots of interest and peptide mass fingerprinting by MALDI-TOF MS were carried out as described in chapter 3.

For Tandem MS, the protein spots were digested the same way as for peptide mass fingerprinting. The samples were purified and concentrated using ZipTips as previously described (chapter 3), except that the TFA solution was replaced by formic acid (10%). 1 µl of the concentrated sample was loaded into a capillary needle (Protana). The capillary

needle was linked to the Tandem MS and voltage was applied to enable the spray of the sample (nano-electrospray).

The Tandem mass spectrometer used in this study (Q-STAR) contains two analysers, separated by a collision cell. Peptide mass fingerprints were acquired in the first analyser (TOF-MS scan), the high intensity peptides were then specifically selected, fragmented in the collision cell and the mass of the fragment ions were measured in the second analyser, producing peptide sequence information.

The Tandem mass spectra were acquired in the following way. The TOF-MS scan was run for 10 s and detected doubly, triply and quadruply charged ions whose mass to charge ratio (m/z) was between 400 and 1,000. From this, mass spectra were acquired using a data-dependent acquisition mode in which each full scan mass spectrum generated by the TOF-MS was followed by collision-induced dissociation of the eight most intense parent ions whose signal had reached a threshold of 20 counts/s. Acquisition was performed with the dynamic exclusion of m/z ratios of already fragmented ions. The fragmentation was performed in positive polarity using nitrogen as the collision gas. Mass spectra were acquired for 15 s in the range of 50 to 2,000 m/z. The resulting peptide MS/MS spectra were interpreted using the MASCOT® search engine to search the NCBInr and a local *T. brucei* database to identify the genes encoding the particular protein. Partial carboxymethylation of cysteine residues and oxidation of methionine residues were considered in the search.

6.2.4 Molecular biology methods

6.2.4.1 Sequencing

Once the sequence of the gene encoding the protein of interest was identified, primers were designed to allow amplification of the complete coding sequence. Each ORF was cloned using primers 274F/274R and 277F/277R (Figure 6.2, Table 6.1). PCR was performed, on genomic DNA from 386 and 386Mr lines, in 40 µl reaction volume containing, 4 µl of Custom MasterMix buffer, 5 µM of each primer, 200-300 ng of DNA template and 4 units of Taq polymerase. Amplification was performed on a robocycler (Stratagene) by denaturing at 95°C for 50 s, annealing at 63°C for 50 s and extension at 68°C for 2 min for 30 cycles followed by incubation at 68°C for 15 min. The PCR product was run on a 1% agarose gel and extracted from the gel using the QIAquick™ gel extraction kit, according to the manufacturer's instructions. Cloning was performed using the TOPO vector and competent *E. coli* TOP 10 cells. Insertion of the PCR product into the TOPO vector was performed by mixing 1 ng of TOPO vector with the PCR product (1 µl) in water (final volume of 5 µl) and incubating at room temperature for 5 min. 1 µl of this cloning reaction was added to a vial of competent *E. coli* TOP 10 cells and incubated on ice for 30 min. Transformation of the competent cells was performed using the heat shock method (42°C for 30 s followed by 4°C for 2 min). Luria Bertani (LB) medium (250 µl) was then added to the vials which were incubated at room temperature for a further 30 min. Selection of recombinant *E. coli* cells was undertaken on LB agar plates containing Ampicillin (0.4mg/ml) and X-gal (5 µg/ml, 5-bromo-4-chloro-3-indolyl-β-D-galactoside) at 37°C overnight. Single colonies were picked and grown in 10 ml of LB medium containing Ampicillin (0.4 mg/ml) at 37°C overnight. *E. coli* cells from 3 ml of culture were concentrated in an Eppendorf by centrifuging at 12,000 g for 3 min. The TOPO vector

Table 6.1: List of primers for the analysis of ORF 274 and 277. Sequence of primers used for the analysis of ORF 274 and ORF 277, and the production of anti-CAR antibodies, with the amplification conditions are given. Denaturation for all PCR was performed at 95°C for 50 s.

containing the insert was extracted from the *E. coli* clone using the QIAGEN plasmid minikit according to the manufacturer's instructions. To assess the presence of the insert in the TOPO vector, 3 µl of plasmid was digested with EcoRI (250 U) in 15 µl of ddH_2O containing 2 µl of EcoRI buffer at 37°C for 2 h. Digestion products were analysed by agarose gel electrophoresis on a 1% agarose gel. Plasmids containing the correct size insert were precipitated using 3 M Sodium acetate ($1/10^{th}$ volume) and 100% ethanol (2 volumes) by incubating at -20°C overnight (Sambrook *et al.*, 1989). The selected clones and the primers were then sent for sequencing to the MBSU of the University of Glasgow.

6.2.4.2 Analysis of transcription

6.2.4.2.1 RNA extraction

Extraction of RNA from procyclic culture was performed under sterile conditions in a culture hood. 27 ml of procyclic cultures at $7x10^6$ trypanosomes/ml were centrifuged for 8 min at 12,000 g to collect $1x10^8$ trypanosomes. The pellet was washed once in PSG buffer and then re-suspended in 1 ml of Trizol. Following 5 min incubation at room temperature, 0.2 ml of chloroform was added to the solution, the tubes were shaken vigorously and then incubated for a further 2 min at room temperature. The phases were separated by centrifuging at 4°C for 15 min at 12,000 g and the aqueous phase was transferred into a clean Eppendorf to which 0.5 ml of isopropanol was added, mixed well and incubated at room temperature for 10 min. The RNA was pelleted by centrifuging the tubes at 4°C for 10 min at 12,000 g, and then washed in 75% ethanol prepared in diethyl pyrocarbonate (DEPC) treated water. The pellet was air-dried, re-suspended in 100 µl of DEPC treated water and treated with DNA-free™ kit (Ambion) according to the manufacturer's instructions.

6.2.4.2.2 RT-PCR

Total complementary DNA (cDNA) was prepared from RNA dissolved in DEPC treated water using an oligo $(dT)_{15}$ primer for first strand synthesis. The total cDNA from the RNA was produced by incubating the PCR tubes containing the RNA on a robocycler (Stratagene) at 70°C for 10 min and then at 4°C for 1 min. To each tube, 4 µl of 5x first strand buffer, 0.01 M of DTT, 10 µM of dNTP mix and 1 µl of Rnase out was added. After the tubes were incubated at 42°C for 5 min, 1 µl of Superscript RT was added. The solution was covered with 6 µl of mineral oil to prevent evaporation of the solution. Tubes were incubated at 46°C for 50 min, followed by 70°C for 15 min and then stored at -20°C. This total cDNA was then used as a DNA template in PCR reaction using primers 274F/274R and 277F/277R to assess the transcription of ORF 274 and 277. The amplification was performed as described in section 6.2.4.1 except that the last elongation step (68°C for 15 min) was removed.

6.2.4.2.3 Northern blot analysis

The RNA extracted from trypanosomes was run on a 6% formaldehyde gel. Gels were made by mixing 2% melted agarose with 12% formaldehyde in 20x Northern gel buffer (0.036M Na_2HPO_4, 0.004M NaH_2PO_4). 3 µl of the RNA samples were mixed with 3.5 µl of formaldehyde, 10 µl of formamide, 1 µl of 20xNorthern gel buffer and double distilled water to a final volume of 20 µl. The samples were incubated at 55°C for 15min and chilled on ice. 2 µl of RNAse-free loading buffer (50% glycerol, 1 mM EDTA pH8, 0.25% Bromophenol blue, 0.25% Xylene cyanol FF) was added to the samples, and the samples were loaded onto the gel. The gel was run at 60 V for 6 h and then incubated in 20x SSC (0.3 M Tri-sodium citrate, 3 M sodium chloride, pH 7.0) at room temperature for 30 min. The RNA was transferred onto a Hybond-N nylon membrane at room temperature overnight (Sambrook *et al.*, 1989). Cross-linking of the RNA onto the membrane was performed in a Spectrolinker XL-100 UV crosslinker (Spectronics Corporation). The

membrane was incubated in the pre-hybridisation solution (7.5 ml formamide, 3.75 ml 20x SSC, 3 ml 50x Dendhart, 0.1 ml NaH_2PO_4 pH 6.5, 0.3 ml HS DNA, 0.15 ml 10% SDS and 0.15 ml 0.5 M EDTA) at 42°C for a minimum of 4 h. The probes were generated by PCR amplification of genomic DNA from the Cymelarsan sensitive 386 line, using primers 274G/274R, 277G/277R and TIM-A/TIM-F (Figure 6.2, Table 6.1). The PCR products were run on a 1% agarose gel and the fragment corresponding to the correct size product were recovered from the gel using the QIAquick™ gel extraction kit according to the manufacturer's instructions. The PCR products were labelled with α ^{32}P (NEN Life Science) using the Stratagene Prime-IT II random primer labelling kit according to the manufacturer's instructions. The labelled probe was purified using a Microspin TM S 200HR column according to the manufacturer's instructions. The probe was denatured for 5 min at 95°C, before being added to the hybridisation solution. Hybridisation was allowed to take place overnight at 42°C. The probe was then removed and the membrane washed in 0.1% SDS and 0.1xSSC at 57°C for 3 cycles of 30 min. The membrane was exposed to a X-ray film for 7 days at -80°C and the autoradiographs were developed using a Compact X4 film processor (X-graph Imaging Systems) according to the manufacturer's instructions.

6.2.4.3 Production of antibody

Antibodies to the expressed product of ORF 274 were produced in mice using a DNA vaccination strategy (Figure 6.3). Mice were first injected with the pcDNA3.1(+) plasmid containing ORF 274 and then with a recombinant protein produced from ORF 274 to boost the antibody response.

6.2.4.3.1 Cloning in pcDNA3.1(+)

The pcDNA3.1 plasmid was donated by Dr Gill Douce (University of Glasgow). The forward primer was designed from the sequence of ORF 274 and modified to contain the Kozak translation initiation sequence, an ATG codon and a HindIII restriction site. The reverse primer was designed from the sequence of ORF 274 and modified to contain a stop codon and a BamHI restriction site, to facilitate cloning in the right open reading frame and forward orientation (Figure 6.4). PCR was performed on genomic DNA from line 927 using these primers in a 40 µl reaction as previously described. The PCR products and pcDNA 3.1 (+) plasmid were digested using HindIII and BamHI restriction enzymes by incubating at 56°C for 1 h. Transformation of Top 10 *E. coli* competent cells with the plasmid and PCR product was carried out as previously described. Single colonies of the transformed *E. coli* cells were picked, grown up in LB medium and the plasmid extracted as previously described. The plasmid from these clones was sequenced by the MBSU of the University of Glasgow, using the BJS 10 and BJS 11 primers (Table 6.1), to determine whether the insert was in frame. One clone, with the insert in frame and in the right orientation, was selected and grown in 100 ml of LB medium containing Ampicillin (0.4 mg/ml). Plasmid DNA was extracted from a 100 ml culture using the EndoFree® plasmid Maxi kit, according to the manufacturer instructions. The purified plasmid was given to Dr Gill Douce (University of Glasgow) for coating onto gold particles and injection into mice by gene-gun technology.

6.2.4.3.2 Expression of recombinant protein in *E. coli* (Gateway system)

The Gateway Cloning Technology is a universal cloning system that takes advantage of the site-specific recombination properties of bacteriophage lambda (Landy, 1989) to provide a rapid and highly effective way to move a gene of interest into multiple vector systems. The Gateway Cloning Technology was used for cloning PCR products flanked by an *att*B

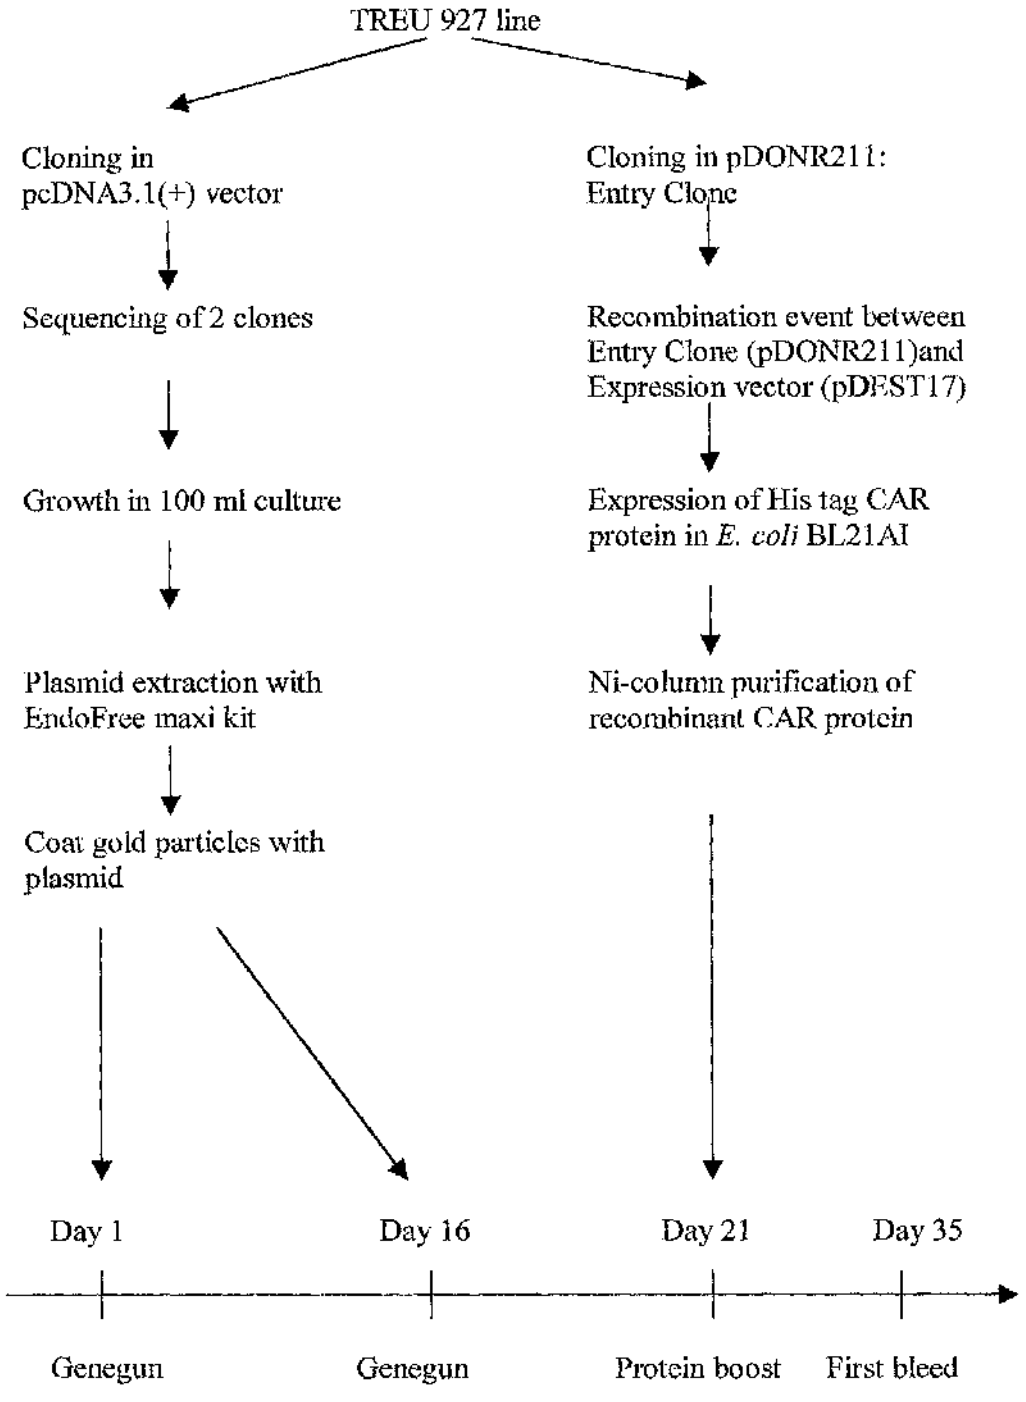

Figure 6.3: **The genegun technology**. Schematic representation of the strategy used to produce antibody against Tryp9.0.000322-274 (CAR gene) from the reference line 927. The mice was injected on day 1 and day 16 with gold particles coated with the plasmid pcDNA3.1(+) containing the Kozak initiation sequence and ORF 274 in frame with the T7 promoter and on day 28 with a purified N terminal His tagged CAR protein.

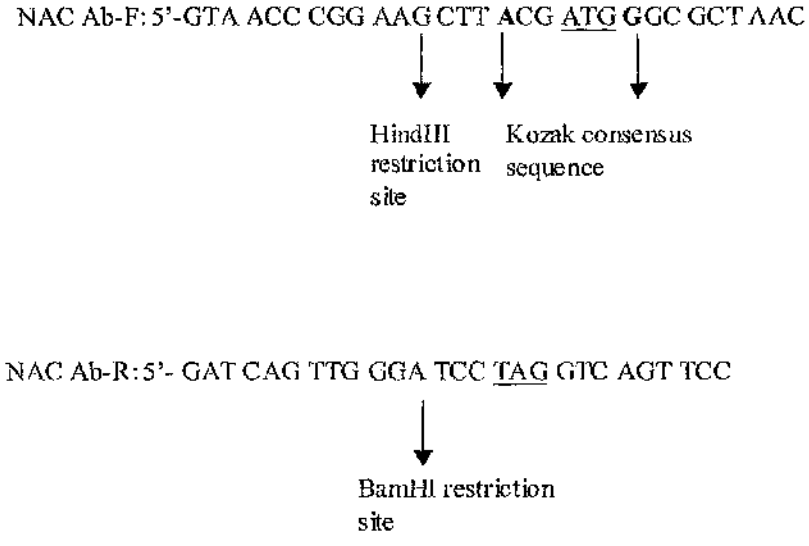

Figure 6.4: Primers for cloning in plasmid pcDNA3.1(+). Sequences of the forward and reverse primers designed to clone ORF 274 in plasmid pcDNA3.1(+) for the production of antibodies in mice. The forward primer contains the start codon (underlined), a HindIII restriction site (blue) and the Kozak translation initiation sequence (bold). The reverse primer contains the stop codon (underlined) and a BamHI restriction site (blue).

recombination sites to generate Entry Clones. Primers were designed to contain the *attB* recombination sites in frame with the start codon (forward primer) and the stop codon (reverse primer). Amplification using these primers was performed on 200-300 ng of DNA from line 927 in a 40 µl reaction, using the conditions described in Table 6.1. The PCR products were run out on a 1% agarose gel and the band corresponding to the predicted size of ORF 274 was extracted from the gel using the QIAquick™ gel extraction kit and purified using 30% PEG 8000/ 30 mM $MgCl_2$. The Entry Clone was generated using the purified PCR product and the pDONR211 plasmid with insertion into the plasmid being undertaken according to the manufacturer instructions. This plasmid was used to transform DH5α competent cells and recombinant cells were selected on LB agar plates containing Kanamycin (50 µg/ml). Single colonies were picked and grown in LB medium containing Kanamycin (50 µg/ml), and the plasmid was extracted from 3 ml of culture using the QIAGEN plasmid minikit.

The Entry Vector was generated by a recombination event between the pDONR211 plasmid, containing ORF 274 from trypanosome line 927, and the pDEST 17 vector containing a T7 promoter and 6 histidines at the N terminus. The recombinant pDEST17 vector was introduced into BL21AI competent cells. Recombinant cells were selected on LB agar plates containing Ampicillin (100 µg/ml) by growth at 37°C overnight. Single colonies were then grown in LB medium at 37°C. The recombinant protein was expressed by growing the transformed BL21AI cells on LB medium containing Ampicillin (100 µg/ml) at 37°C for 3 h on a shaker. Expression of the recombinant protein was induced by addition of L-arabinose in the culture medium and incubation at 37°C for 4 h. The cells were pelleted (4°C for 15 min at 12,000 g) and stored at -20°C. Recombinant protein, from the induced BL21AI cells, was extracted by sonicating the cells in Binding buffer (10 mM

Tris-HCl pII 7.8, 5 mM Imidazole, 0.5 M NaCl, 10% glycerol) on ice 20 times for 30 s. The recombinant protein was purified from the extract using affinity chromatography on Ni-NTA agarose according to the manufacturer's instruction. The purity of the eluted protein was assessed by running the fractions on a 12% SDS-PAGE gel. The gel was stained with Coomassie Brilliant blue.

Antiserum to the recombinant protein was obtained from female mice immunised by a genegun injection of plasmid pcDNA 3.1 (+) containing ORF 274 (day 1 and 16) followed by intraperitoneal innoculation of a booster of 0.2 mg/ml recombinant protein with 0.1 ml of complete Freund's adjuvant. All injections and bleeding of the mice were performed by Dr Gill Douce. A first bleed was obtained after 35 days, and the production of antibody tested by Western dot blot analysis against the recombinant CAR protein (data not shown). The final bleed was made on day 45.

6.2.4.3 Western blot analysis

Western blot analysis of proteins separated onto SDS-PAGE gels were carried out as described in chapter 2.

6.3 Results

6.3.1 Comparative proteomic analysis of Cymelarsan sensitive and resistant *T. brucei* using broad pH ranges

In order to compare the protein expression profiles of Cymelarsan sensitive and resistant lines of 386, soluble proteins extracted from procyclic cultures were separated by 2DE. Proteins extracted from $1x10^8$ procyclic form parasites were separated in the first

dimension according to their isoelectric point, on IPG strips (pH 4-7), and then by molecular weight on a 12% polyacrylamide gel. After staining the gels with Sypro ruby, they were compared by subtractive analysis, using the ImageMaster 2DElite software. The comparison showed that, out of 485 proteins separated on the 2D gels, there was only one protein spot (spot 2) differentially expressed between the lines (Figure 6.5). The protein spot present in the soluble protein extract of 386, at about pI = 4.5, was absent from the extract of the 386Mr line. This protein spot was located adjacent to a protein spot, present in both lines, with approximately the same molecular weight but a more acidic pI (spot 1).

In order to ensure that the difference observed between 386 and 386Mr lines was not due to minor differences in sample preparation, further protein extractions were made from procyclic form parasites. These were separated by 2DE, as before, and stained with either Sypro ruby or Coomassie Brilliant blue. Nine independent soluble trypanosome protein extracts were run on 2D gels, all of which consistently revealed the absence of the protein spot around pH 4.5 in the 386Mr line (Figure 6.6A and 6.6B). This confirmed that the differentially expressed protein spot was not due to sample preparation. In addition, the missing protein spot could not be detected in the 386Mr protein extracts using either the insensitive Coomassie Brilliant blue staining or the sensitive Sypro ruby staining. This suggests that the observed difference was not an artifact due to variation in sample loading.

2D gels were run using soluble protein extracts from procyclic forms of 386Mr line growing in 1 μM of Cymelarsan in SDM79 (Figure 6.6C). These gels also revealed the absence of the protein spot around pH 4.5 in the 386Mr line growing in the presence of the

Close-up of a section of the gels between pH 4.4 and 4.6 from 2D gels on broad pH range IEF (pH 4-7) for 386 (A), 386Mr (B) and 386Mr growing in the presence of 1 μM Cymelarsan (C). Soluble proteins, from $1x10^8$ parasites grown in SDM79, were separated on pH 4-7 2D gels and stained with Coomassie Brilliant blue. An arrow indicates the differentially expressed protein spot (spot 2).

drug. No other difference in the 2D protein pattern was observed in over 485 protein spots separated by 2DE and visualised by Sypro ruby staining.

6.3.2 Comparative proteomic analysis of Cymelarsan sensitive and resistant *T. brucei* using narrow pH ranges

With complex samples, such as the whole cell extract employed in this study, 2DE analysis on wide-range pH gradient reveals only a small percentage of the whole proteome because of insufficient spatial resolution. The use of narrow range focusing gels can provide increased resolution of proteins with similar electrophoretic mobilities. Zoom-in gels in the pH range between 4 and 7 (IPG 4-5, 4.5-5.5, and 5.5-6.7) were used in the first dimension separation to increase the resolving power of 2DE on whole cell extracts from procyclic forms of the two isogenic lines.

6.3.2.1 Analysis of Cymelarsan resistance on pH 4-5

To determine whether other proteins were differentially expressed between the pair of isogenic lines, whole soluble protein extract from procyclic forms were separated on a narrow pH range gel of pH 4 to 5. The gels were stained with Coomassie Brilliant blue, compared and one differentially expressed protein spot detected between the lines. One protein spot (at approximately pI = 4.5) on the 2D pattern of proteins from the 386Mr line was missing when compared with the 2D gel separation from the 386 line. On the gel from the 386 line this protein spot was located adjacent to a second protein spot, present in both lines, which had approximately the same molecular weight but a more acidic pI (data not shown).

6.3.2.2 Analysis of Cymelarsan resistance on pH 4.5-5.5

Proteins extracted from $1x10^8$ procyclic stage trypanosomes were separated on narrow isoelectric focusing, pH 4.5 to 5.5 strips, prior to separation according to their molecular weight on 12% polyacrylamide gels. Analysis of the Coomassie Brilliant blue stained gels using the ImageMaster 2DElite software revealed almost 200 spots on each gel (157 spots on the 386 gel, 198 spots on the 386Mr) (Figure 6.7A and 6.7B). The protein patterns were very similar for the two lines. The variation in the number of protein spots detected was due to very faint spots which were not detected in the extract from 386. As this was only observed for the faint spots it is likely that these differences were due to a difference in quantity of protein loaded rather than real variation between the samples associated with Cymelarsan resistance. This was confirmed by the fact that the differences in protein detected on these gels were not reproducible, based on the analysis of three independent extractions.

6.3.2.3 Analysis of Cymelarsan resistance on pH 5.5-6.7

Soluble proteins from $1x10^8$ of procyclic forms of the 386 and 386Mr lines were extracted and separated on 2D gels as described above but using a narrow pH range of pH 5.5-6.7 for IEF. Analysis of the Coomassie Brilliant blue stained gels using the ImageMaster 2DElite software revealed the presence of 124 protein spots on the gel from the 386 line and 104 protein spots on the gel from the 386Mr line. Most of the protein spots missing on the gel from sensitive parasites corresponded to very faint spots detected in the 386Mr line. These were likely to be missing from the resistant protein separation due to the difficulties in loading exactly the same amount of protein from both lines. Subtractive analysis of the 2D gels revealed that a highly abundant protein spot present in the extract of the 386 line was missing from the extract of the 386Mr line (Figure 6.8A and 6.8B). This protein spot (spot

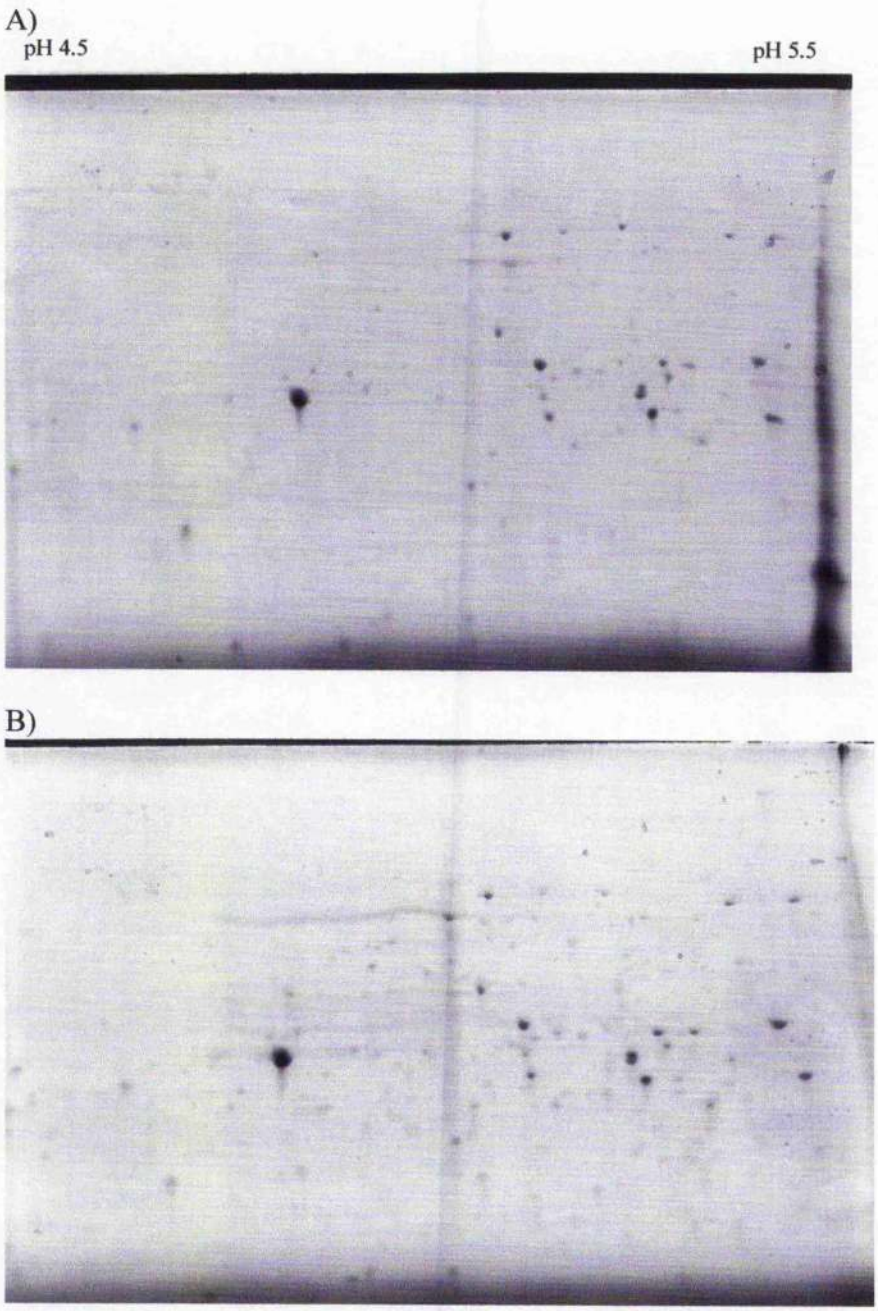

Figure 6.7: 2D gels of procyclic forms of isogenic 386 lines, pH 4.5-5.5. Narrow pH isoelectric focusing (pH 4.5 to 5.5) 2D gels of 386 (A) and 386Mr (B) lines. Soluble proteins from $1x10^8$ procyclic parasites grown in SDM79 were separated by 2DE. Subtractive analysis of Coomassie Brilliant blue stained 2D gels revealed no difference in protein expression pattern between the two isogenic lines.

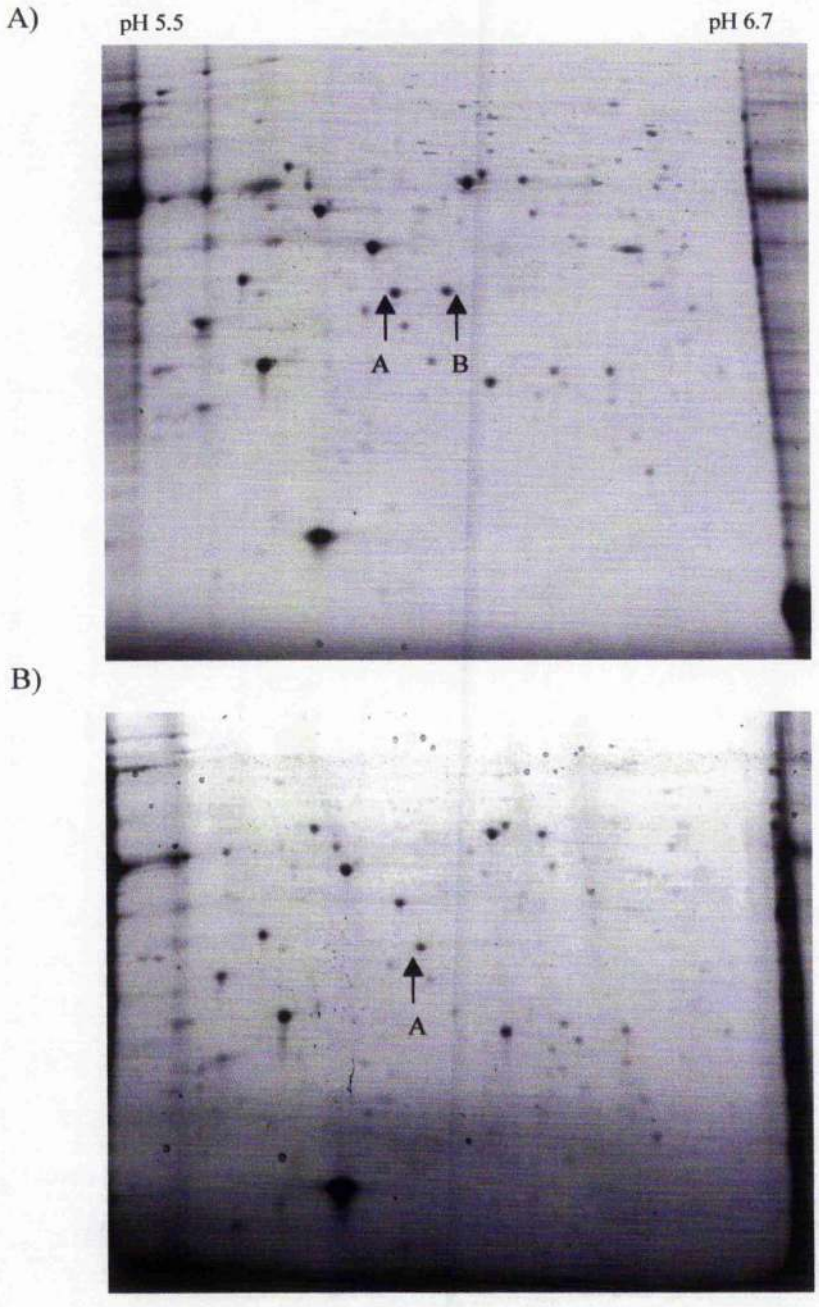

Figure 6.8: 2D gels of procyclic forms of isogenic 386 lines, pH 5.5-6.7. Narrow pH isoelectric focusing (pH 5.5 to 6.7) 2D gels of 386 (A) and 386Mr (B) lines. Soluble proteins from $1x10^8$ procyclic parasites were separated onto the 2D gel prior to Coomassie Brilliant blue staining. Subtractive analysis of the 2D gels revealed one protein spot differentially expressed (spot B) between the isogenic lines of 386.

B) had a pI of around 5.8 and in the sensitive line was adjacent to another protein spot (spot A), present in both lines, with a similar molecular weight but a more acidic pI. Due to technical difficulties with the 2DE system, this experiment was not repeated.

Taken together, the results from the 2D analysis demonstrated that two protein spots were differentially expressed between the procyclic stages of the pair of isogenic lines of 386 from over 1,000 protein spots analysed both on broad and narrow pH ranges. The two differentially expressed protein spots were visible on Coomassic Brilliant blue stained gels, suggesting that they were highly abundant in the cell. The absence of protein spot 2 (pI 4.5), in the protein extract of the 386Mr line, was confirmed in nine independent protein extractions separated on pH 4-7 gels and also on the narrow pH 4-5 range gel. The absence of spot B (pI = 5.8) in the protein extract of the 386Mr line was only shown in one experiment. Both spot 2 and spot B are adjacent to spots with similar molecular weight but a more acidic pI, suggesting that spot B could be an isoform of spot A and spot 2 could be an isoform of spot 1.

6.3.3 Identification of differentially expressed proteins

The mass spectrometry techniques, MALDI-TOF and Tandem MS, were used to determine the identity of the differentially expressed protein spots observed by 2DE between the procyclic forms of Cymelarsan sensitive and resistant 386 lines.

The differentially expressed protein spots detected on pH 4-7, pH4-5 and pH 5.5-6.7 gels, as well as nearby protein spots, were excised from the gels, digested with trypsin and analysed by mass spectrometry. Mass spectra were acquired initially by MALDI-TOF MS to provide a peptide mass fingerprint. In addition, Tandem MS was also carried out to confirm the identification obtained by PMF and to identify spots for which no

identification was obtained by PMF analysis. One of the mass spectra obtained from Tandem MS analysis of spot 1 from the 386 line and corresponding to peptide sequence FPGNTTFLIFGEAQLGDTTMQTQEAAAR is given as an example in Figure 6.9. PMF and peptide sequence tag were performed on five protein spots from the 386 line and four proteins from the 386Mr line, excised from pH 4-7 gels (Figure 6.10A and 6.10B). Analysis of the peptide mass fingerprints was carried out using the MASCOT® search engine on the NCBInr and the local *T. brucei* databases. Protein spot 4 and 5 from both 386 and 386Mr lines were identified as β tubulin (gi number: 9366734) (Figure 6.10C). No identity could be assigned to either protein spot 1 or 2 by searching either the NCBInr or the local *T. brucei* databases with their peptide mass fingerprints (Figure 6.10C). Analysis by Tandem MS confirmed the identity of spot 4 and 5 for both 386 and 386Mr lines as β tubulins, with scores of 204 and 469 for the 386 line and 142 and 437 for the 386Mr line (Figure 6.10C). Tandem MS analysis on spot 3 enabled its identification as another β tubulin (gi number: 9366734) with a score of 74 and 143 for the 386 and 386Mr line respectively (see Appendix IV). Using the sequence information generated by Tandem MS no identification for protein spots 1 and 2 could be made searching the NCBInr database. The MASCOT® search engine was then used to search the local *T. brucei* database. The two protein spots (spot 1 and 2) from the 386 line and the corresponding protein spot (spot 1) from the 386Mr line, all matched a putative open reading frame, accession number Tryp9.0.000322-274 (GeneDB), located on Chromosome IX with scores of 123, 178 and 217 respectively (Table 6.2). The differentially expressed protein spot, and the adjacent spot, detected on pH4-5 gels were analysed by Tandem MS and found to both match onto Tryp9.0.000322-274 (data not shown).

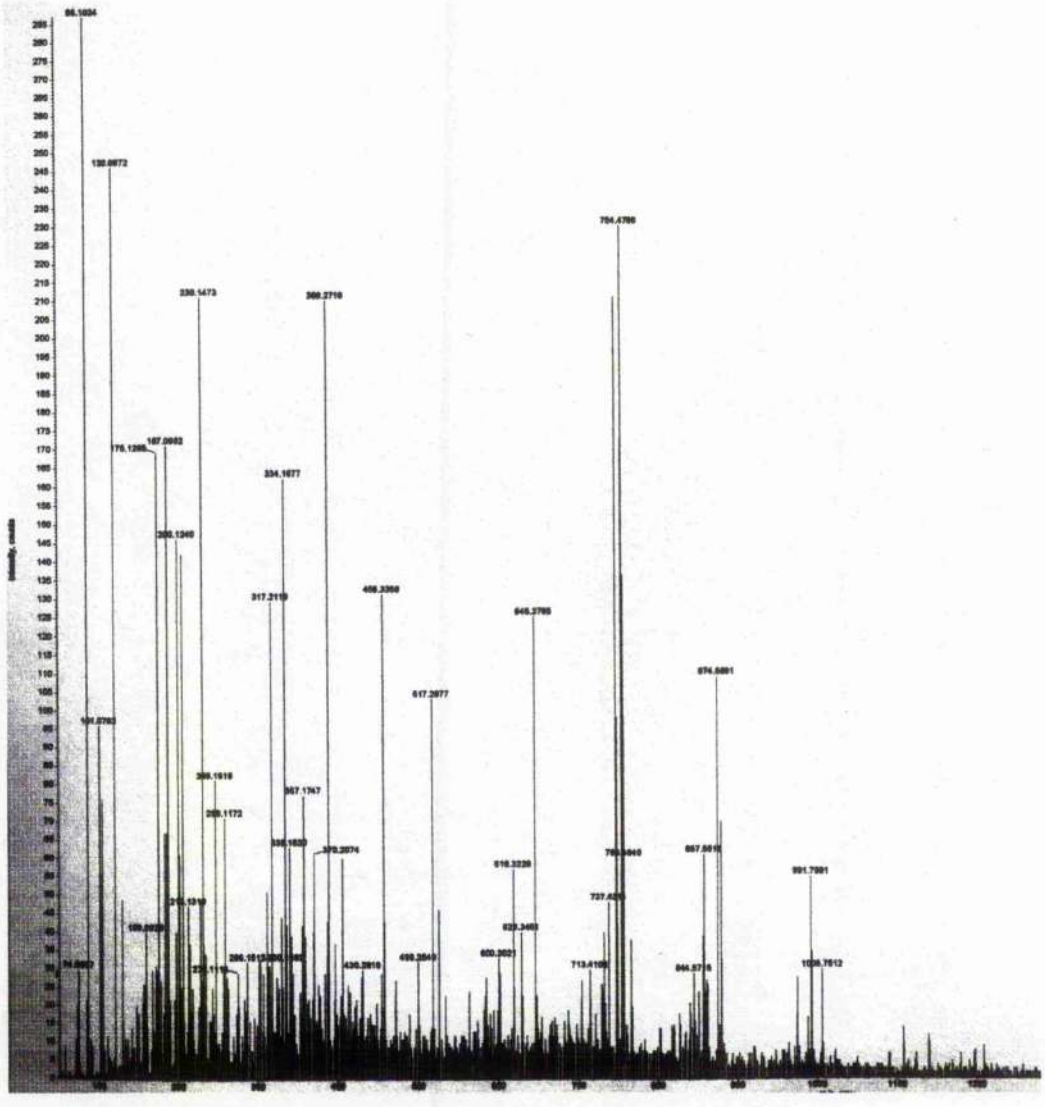

Figure 6.9: **Example of a Tandem mass spectrum**. Tandem mass spectrum of the tryptic, micropurified peptides derived from in gel digestion of protein spot 1 from 386Mr 2D gel. The parent peptide (1528.4 Da) was selected out of the mixture in the first analyser and was then dissociated by collision with nitrogen. The resulting fragments were separated in the second analyser producing the Tandem mass spectrum. The spectrum gives the mass to charge ratio (m/z) of the tryptic peptide against their intensity. Ions generally have a charge state corresponding to the number of positively charged amino acid plus the charge formally localized at the N terminus of the peptide. Thus tryptic peptides are often doubly charged, or triply if they contain a histidyl residue.

Table 6.2: Detailed results from the MASCOT[36] search engine for spot 1 and 2. The table gives the sequence of peptides from the local *T. brucei* database corresponding to the mass spectra obtained from the protein spots. The score indicates the probability that the protein in the database corresponds to the protein from the 2D gel. A score over 23 corresponds to the probability of the protein from the database to be a random match of less than 5% ($p<0.05$).

Mass spectrometry analysis was performed on the differentially expressed protein spot and surrounding protein spots from the narrow (pH 5.5-6.7) range strips (Figure 6.11). Four protein spots from the 386 line and three protein spots from the 386Mr line (Figure 6.11A and 6.11B) were excised from the 2D gels and digested with trypsin. Tandem MS analysis was performed on the tryptic peptides. The mass spectra obtained were searched against the NCBInr and the local *T. brucei* databases using the MASCOT® search engine. The protein spots surrounding the differentially expressed protein, were identified with high confidence as an enolase (spot C) and a pyridoxine kinase (spot D) (Figure 6.11C, Appendix 4). The differentially expressed protein spot (spot B) matched onto an arginine kinase (score = 510). Spot A from the 386Mr, adjacent to spot B on the 386 2D gel, was also identified as an arginine kinase (score = 487). Three gene copies of arginine kinase are present in the *T. brucei* genome (ORF 342, 343 and 345) with high homology to each other. One peptide, sequenced from both spot A and B by Tandem MS, showed that spot A and B are not isoforms as they matched onto different ORFs (Table 6.3). Spot A matched onto ORF 345 while spot B match onto either ORF 342 or 343. These results suggest that unlike the CAR protein, spot A and B are not transcripts of the same ORF that have been modified post-translationally. No identification was made for spot A of the 386 line due to the loss of the sample during Tandem MS analysis.

The analysis of the protein spots separated by 2DE using mass spectrometry enabled the identification of the differentially expressed protein spots. Spot 2 from gel pH 4-7 and from gel pH 4-5 were matched onto a non-annotated ORF, which was then designated as the Cymelarsan Resistance Associated protein (CAR protein) and spot B on gel pH 5.5- 6.7 was identified as an arginine kinase. Spot 1, adjacent to the CAR protein on 2D gels of the 386 line and present in both lines, was matched onto the same ORF as the CAR protein,

Table 6.3: Detailed results from the MASCOT® search engine for spot A and B. The table gives the sequence of peptides from the local *T. brucei* database corresponding to the mass spectra obtained from the protein spots. The score indicates the probability that the protein in the database corresponds to the protein from the 2D gel. A score over 53 in this case corresponds to the probability of the protein from the database to be a random match of less than 5% ($p<0.05$). One identified peptide, highlighted in blue, enabled to differentiate ORF 345 from ORF 342 and ORF 343.

suggesting that spot 1 was an isoform of the CAR protein. Spot A and B were both identified as arginine kinase. However, the Tandem MS analysis demonstrated that spot A matched onto ORF 345 while spot B matched onto either ORF 342 or ORF 343. These results would suggest that the transcript of either ORF 342 or ORF 343 (or both) is present in the 386 line but not in the 386Mr line at pH 5.8 on the 2D gel.

6.3.4 Molecular analysis of the CAR locus

6.3.4.1 Presence of the CAR gene in the isogenic 386 lines

The CAR protein was found to be differentially expressed between 386 and 386Mr lines. It was located at around pH 4.5 on 2D gels and was matched onto a putative ORF (Tryp9.0.000322-274) from the reference line 927. BLAST searches in GeneDB using the sequence from this protein revealed that there was another copy of the gene situated upstream from Tryp9.0.000322-274, called Tryp9.0.000322-277. These ORFs will thereafter be referred to as ORF 274 and ORF 277. Both copies have identical nucleotide (564 bp) sequences in the reference line 927. No signal peptides or transmembrane domains were found in the predicted protein sequence. Searches with the programs InterPro and Pfam (available at http://ca.expasy.org/tools/) showed the presence of a Nascent polypeptide Associated Complex domain (NAC domain) at the N terminus (amino acid residues 29-88) and an UBiquitin-Associated domain (UBA domain) at the C terminus (amino acid residues 146-186) (Figure 6.12). The DNA and corresponding amino acid sequence of ORF 274 from the reference line 927 are given in Figure 6.13.

In order to confirm the presence of the two ORFs in 927 and investigate whether both homologues occur in the 386 and 386Mr lines, primers were designed to the 5'UTR of

Figure 6.13: Schematic representation of the DNA and amino acid sequences of ORF 274 from *T. brucei* line 927. Two domains were predicted by PedictProtein (http://cubic.bioc.columbia.edu/predictprotein/) in the ORF. A nascent polypeptide associated domain (NAC domain, underlined) and an ubiquitin-associated domain (UBA domain, underlined). Peptides, from trypsin digestion of spot 1 from 386Mr line, sequenced by Tandem MS matching onto the theoretical peptides from the translated ORF 274 are highlighted in blue.

ORF 274 and 3'UTR of ORF 277. PCR amplification of 927 genomic DNA was predicted to give a 2 Kb product that should contain two EcoRI sites and one BamHI site. PCR amplification of 927 genomic DNA confirmed the size prediction and digestion with EcoRI and BamHI confirmed the presence of the restriction sites. The same experiment carried out on genomic DNA from 386 and 386Mr lines confirmed the presence of the two ORFs in these lines (Figure 6.15). This experiment demonstrated the potential presence of two ORFs, identical to each other in the genome reference line 927, potentially each encoding the CAR protein in 386 and 386Mr lines.

A mutation in the ORF of one of the lines could account for the disappearance of a CAR protein isoform on 2D gels of the 386Mr lines. This possibility was assessed by cloning and sequencing the genes. An alignment of the ORFs and their 3' and 5'UTR regions was performed to identify regions of low homology which could be used to design ORF specific primers. As there is no robust bioinformatic method of identifying the precise boundaries of 3' and 5'UTRs, 287 bp upstream and 233 bp downstream of ORF 274 was compared with 171 bp upsteam and 260 bp downstream of ORF 277. The alignment of the ORFs confirmed the 100% homology in the translated region of the genes. The 5'UTR was shown to be highly conserved over 116 bp upstream of the start codon whereas only 19 bp aligned in the 3'UTR regions. These regions were followed by highly divergent sequences, which were used to design the ORF-specific primers (Figure 6.16). Analysis of the sequence of the expected PCR product for ORF 274 and ORF 277 using these primers enabled the detection of a BsaJI restriction site present at different positions in the 3'UTR of the ORFs, 27 bp downstream the codon stop of ORF 274 and 137 bp downstream of the codon stop of ORF 277 (Figure 6.16). The digestion of the PCR products, amplified using the ORF specific primers, with the restriction enzyme BsaJI, generating fragments of the

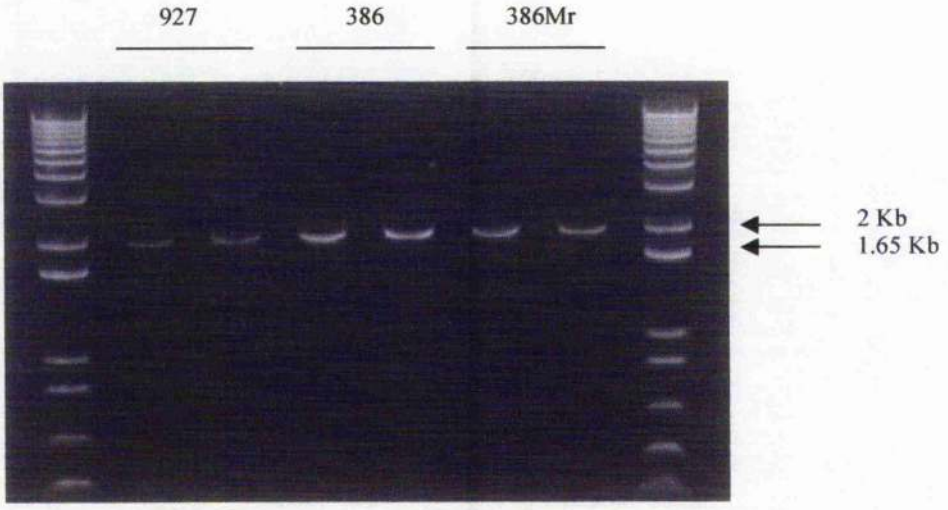

Figure 6.14: PCR amplification of the tandem repeat of ORF 274 and 277. PCR performed on line 927, 386 and 386Mr using primers Tryp9/11 and Tryp9/12, amplified a DNA fragment containing both open reading frames. The 2 Kb PCR product (expected size from reference line 927 database) was recovered for all three lines.

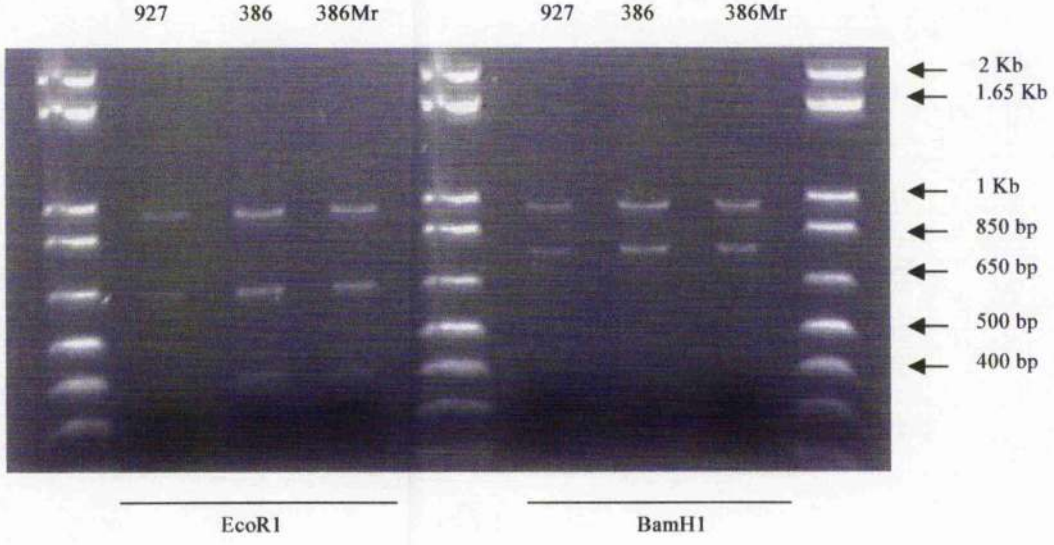

Figure 6.15: RFLP analysis on the tandem repeat of ORF 274 and 277. Digestion of the 2 Kb PCR product using the restriction enzymes EcoRI and BamHI. The restriction fragments corresponded to the predicted sizes of EcoRI digestion (968 bp, 641 bp and 391 bp) and BamHI digestion (968b bp, 764 bp and 269 bp).

Figure 6.16: **Alignment of ORF 274 with ORF 277 from line 927.** The start and stop codon for each ORF are highlighted in blue. The divergent sequences in the 3' and 5'UTR regions were used to design ORF specific primers (underlined sequences). The BsaJ1 restriction sites are highlighted in red.

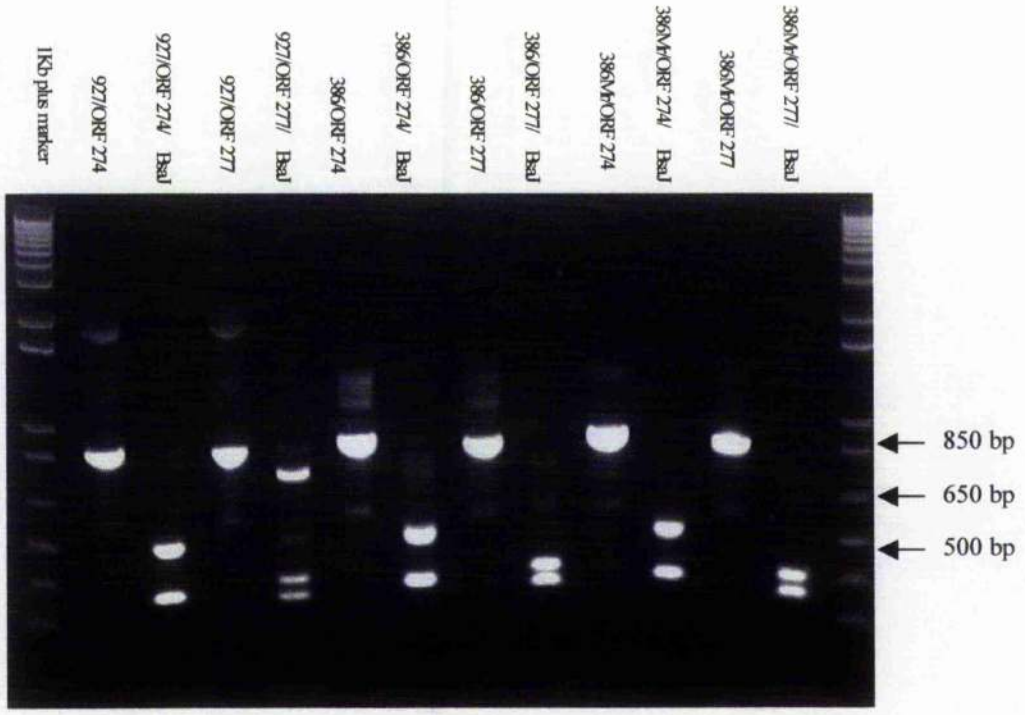

Figure 6.17: **Specificity of the primers designed for ORF 274 and 277**. PCR using the ORF specific primers on genomic DNA from 927, 386 and 386Mr amplified a fragment of the expected size (ORF 274: 891 bp and ORF 277: 868 bp). The PCR product from each ORF was digested using the BsaJI restriction enzyme. The digestion products corresponded to the expected sizes (ORF 274: 370 bp and 500 bp and ORF 277: 123 bp, 350 bp and 395 bp).

expected sizes for each ORF (Figure 6.17). Both ORFs from 386 and 386Mr lines were cloned, using the ORF specific primers, and sequenced to determine whether any nucleotide difference could be detected. Differences between sequences of different clones of ORF 274 were observed which appear consistent with allelic variation (nucleotides highlighted in green, Figure 6.18). Other differences however appear randomly in the sequences and were probably due to PCR errors by the Taq polymerase or sequencing errors. Taken together the sequencing of the ORFs would suggest that both ORF 274 and 277 from the 386 line are identical to their homologues in 386Mr line (Figure 6.18 and 6.19) and that ORF 274 is identical to ORF 277. No mutations were found in the translated gene products of ORF 274 and 277 that could account for the absence of the CAR protein spot (spot 2) in the 386Mr extract detected by 2DE.

6.3.4.2 Transcription of ORF 274 and 277 in the isogenic lines

The sequencing of the two ORFs from both the 386 and 386Mr lines demonstrated that both ORFs were identical. These results suggest that the lack of expression at the protein level of one isoform of the CAR protein is not due to an alteration in coding region of either of the genes. An alternative explanation for the differences at the protein level could be that there are differences in the level of transcripts from the two ORFs between the 386 and 386Mr lines. To analyse this possibility, Northern blot and RT-PCR analyses were performed.

Primers were designed in the 3'UTR regions of each ORF to produce 150 bp long probes which should specifically hybridise to the transcripts from one or the other ORF (Figure 6.1). In the Northern analysis, the membrane was first probed with a PCR product amplified from the coding region for TIM as a positive control. The TIM probe showed the

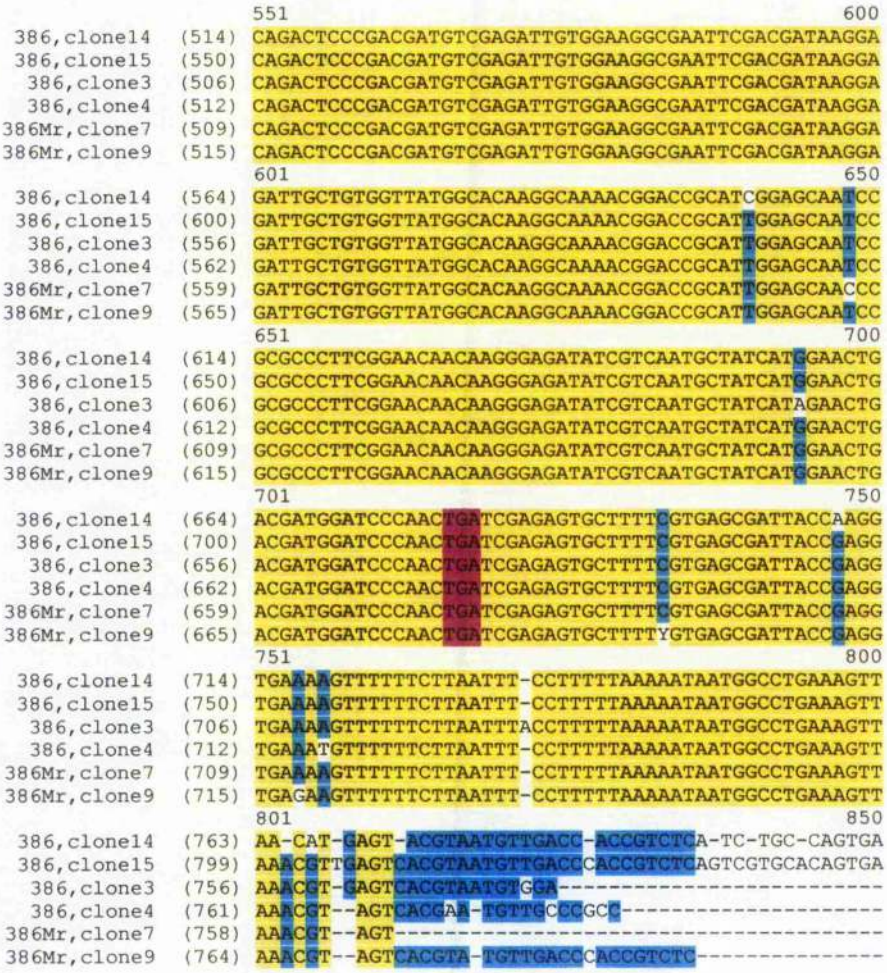

Figure 6.19: **Alignment of ORF 277 sequences from isogenic 386 lines**. Start codon (ATG) and stop codon (TGA) are indicated in pink. The sequences from line 386 (clone 3, 4, 14 and 15) are aligned against sequences from line 386Mr (clone 7 and 9) .

presence of intact RNA molecules on the membrane (Figure 6.20A). PCR products amplified from genomic DNA of line 386, for the coding region of ORF 274 were then used to probe the membrane. This probe gave a faint signal after 8 days exposure (Figure 6.20B). The membrane was then washed and hybridised in succession with probes designed in the 3'UTR of ORF 274 and the 3'UTR of ORF 277. No signal was obtained using these two probes after 8 days exposure. The lack of detection of a signal with the 3'UTR/ORF specific probes could be due to a relatively low level of transcripts from these genes making Northern blot analysis too insensitive. On this basis, RT-PCR analysis was conducted. Total cDNA was synthesized from RNA extracted from 386 and 386Mr lines as described in Materials and Methods. No product was recovered from the PCR amplification performed on the mRNA extract from 386 and 386M showing the absence of contamination in the mRNA extract. PCR amplification from these cDNA preparations was undertaken using primers for the TIM gene (positive control) and the ORF specific primers (274F/274R and 277F/277R). A PCR product corresponding to the predicted size for the ORF was identified for each ORF of 386 and 386Mr lines (Figure 6.21). Thus both ORFs are transcribed in both 386 and 386Mr lines. These results suggest that the absence of the CAR protein observed on 2D gels of the 386Mr line was not due to a mutation or a defect in transcription of one of the two ORFs.

6.3.4.3 Translation of CAR protein and detection of its isoforms

In order to confirm the identity of the CAR protein spot differentially expressed between the isogenic lines, antibodies were raised in mice against the gene products of ORF 274. These were used to identify the protein by Western blotting. The DNA vaccination technique was used in combination with a prime boost strategy to produce antibodies against ORF 274 in mice, as described in Materials and Methods.

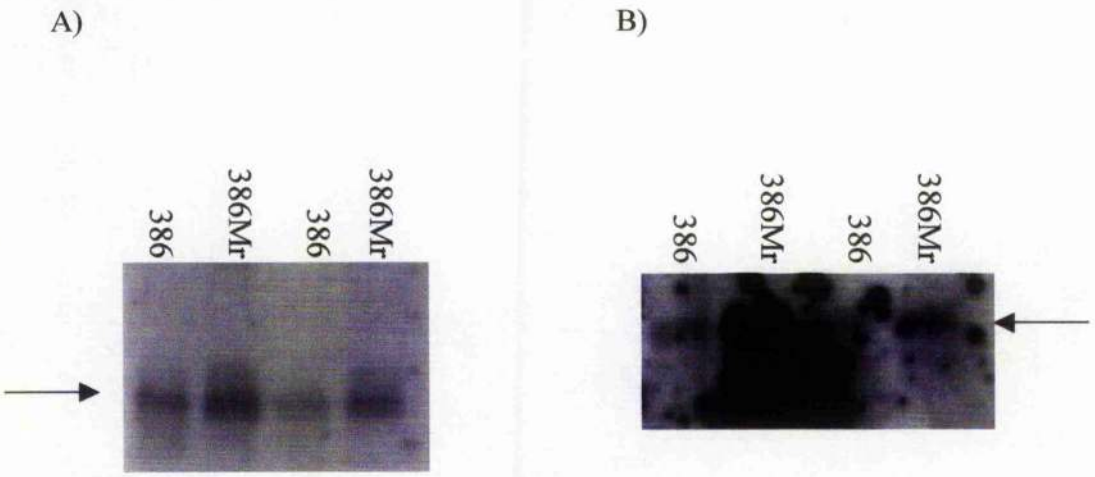

Figure 6.20: **Northern blot analysis for transcription of ORF 274 and 277.** RNA was extracted from procyclic forms of 386 and 386Mr lines. The blot was probed using the TIM product as a loading control (A) and subsequently probed in succession with a PCR product from the coding region of ORF 274 (B), a PCR product from the 3'UTR of ORF 274 and a PCR product from the 3'UTR of ORF 277. No product could be detected using the probes designed in the 3'UTR of the genes.

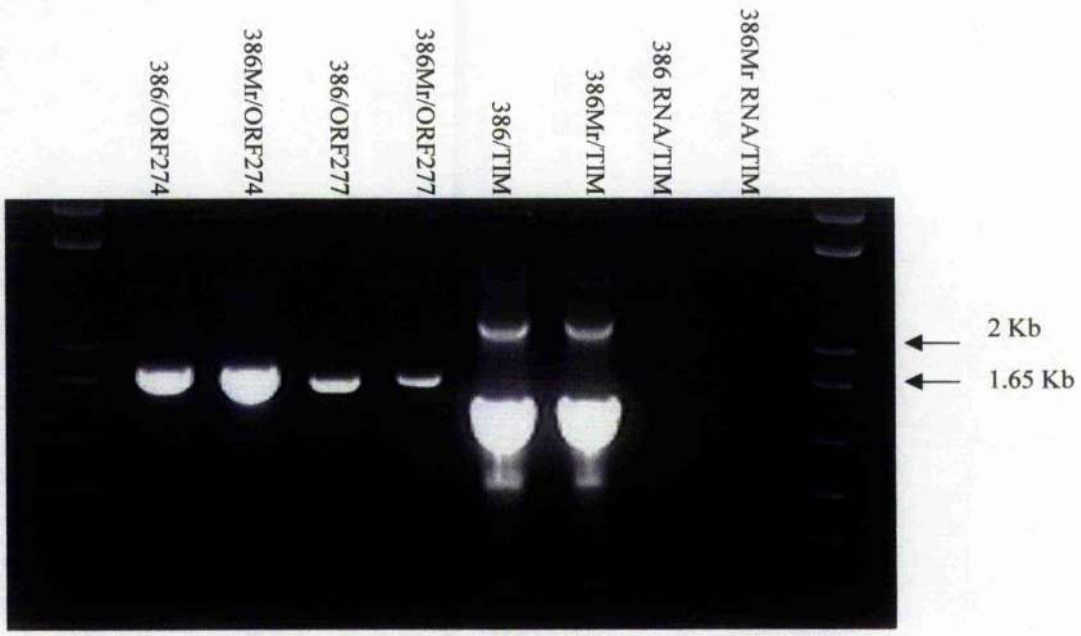

Figure 6.21: **RT-PCR analysis of ORF 274 and 277.** Total cDNA was produced from mRNA extracted from 386 and 386Mr lines. PCR reaction on total cDNA, using the ORF specific primers (274F/274R and 277F/277R), demonstrated the transcription of both ORFs in each line. The TIM primers were used in the PCR reaction as a loading control. No product could be recovered from performing the PCR reaction on the mRNA extract.

The recombinant gene product of ORF 274, to be used for boosting the antibody production, was purified from the bacterial extract using a Ni-NTA agarose column. The elution fractions from the column were run on a 12% SDS-PAGE gel and the gel stained with Coomassie Brilliant blue to assess the production and purity of the recombinant protein (Figure 6.22A). A main band was detected in elution fractions 1 and 2 with a molecular weight of about 34 kDa. This is higher than the predicted gene product size of ORF 274 (20.1 kDa). In order to confirm that this band was the gene product of ORF 274, the band was excised from the gel, trypsin digested and analysed by Tandem MS. The resulting tryptic peptides were analysed by Tandem MS and the mass spectra generated were used to search the local *T. brucei* database with the MASCOT® search engine. The Tandem mass spectra matched onto ORF 274 (score of 213) (Figure 6.22B).

Western blot analysis of whole protein extract from 386 and 386Mr lines separated on SDS-PAGE gel demonstrated the presence of the gene product of ORF 274 in both lines (Figure 6.23A) and the specificity of the antibody produced by the DNA vaccination technique (Figure 6.23B). Detection of isoforms of the gene product of ORF 274 was performed by running whole protein extract on 7 cm 2D gels and transferring the separated proteins onto a membrane. The Western blot analysis revealed the presence of three isoforms of the gene product of ORF 274 at location of 34 kDa and pH 4.5 in the 386 line and only two isoforms at this location in the 386Mr line (Figure 6.24). This experiment confirmed that the CAR protein and spot 1 were the gene products of ORF 274, as previously determined by mass spectrometry analysis. The analysis of isoforms by Western blot on 2D gel revealed the presence of another isoform of the CAR protein located adjacent to the two previously identified isoforms in the 386 line. In addition, two more protein spots were detected in both 386 and 386Mr lines using these antibodies, but these

Figure 6.22: SDS-PAGE gel of purified recombinant gene product of ORF 274. The protein was purified from the *E. coli* cell extract using a nickel NTA agarose column. The fractions from the column were run on a SDS-PAGE gel (A). The band containing the purified protein was excised and digested with trypsin. Summary of the results obtained from the MASCOT® search engine using the Tandem mass spectra generated from tryptic peptides of the purified His-tagged gene product of ORF 274 expressed in *E. coli*. The MASCOT® search engine was used to search the local *T. brucei* database (B). A score over 23 indicates that the probability of the protein from the database to be a random match is less than 5% ($p<0.05$).

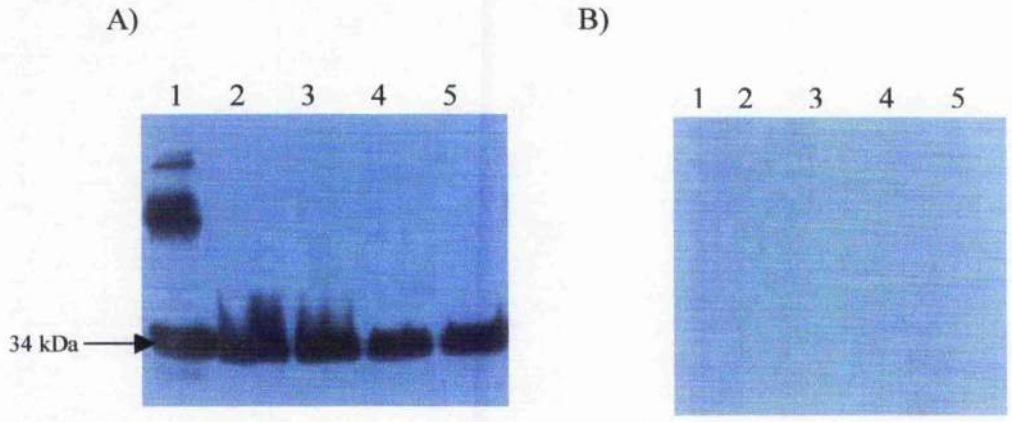

Figure 6.23: Western blot analysis of expression of the gene product of ORF 274 in isogenic 386 lines. Proteins from 386 (lane 2 and 3) and 386Mr (lane 4 and 5) lines were run on SDS-PAGE gels and transferred on a membrane. The gene product of ORF 274 was detected using antiserum from mice (1/167). The antibodies were detected with HRP conjugated anti mouse IgG (1/1,000) and the ECL detection kit. The positive control (lane 1) consisted of the recombinant gene product of ORF 274. Serum from non-immunised mice was used as a negative control (B).

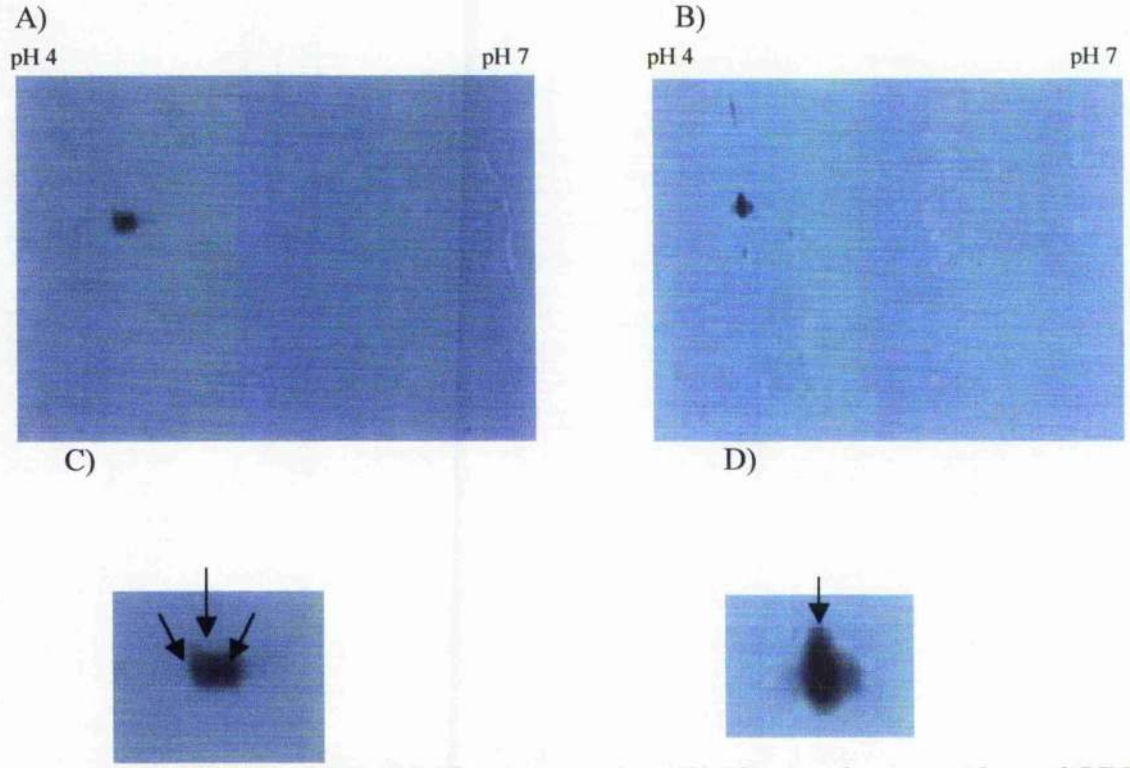

Figure 6.24: Western blot analysis of expression of isoforms of gene product of ORF 274 in isogenic 386 lines. Whole protein extract from 386 (A) and 386Mr (B) lines were separated by 2DE on pH 4-7 gels. The proteins were electro-blotted on a membrane and presence of isoforms was assessed by Western blotting using serum from immunised mice (1/10,000). Close up view of the isoforms of the gene product of ORF 274 detected in the 386 (C) and the 386Mr (D) lines.

were much less intense and were not located at 34 kDa, pH 4.5 (data not shown). These could be degradation products of spot 1 and 2.

6.3.5 Features of predicted amino acid sequence of arginine kinase

The differentially expressed protein spot located at pH 5.8 (spot B) had been identified as arginine kinase from either ORF 342 or 343. The difference in molecular weight and pI of the predicted transcript product from each ORF are shown in Table 6.4. The amino acid sequence of ORF 342 was analysed using the PredictProtein software available at the Expasy web site. The amino acid sequence contained all the characteristic consensus blocks of the guanidino kinase family, and a putative actin binding domain (CPSNLGT) (Figure 6.25). The genes are present as tandem repeat on chromosome IX of the reference line 927.

6.4 Discussion

Whole cell preparations of *T. brucei* proteins could be separated by 2DE into over 1,000 distinct protein spots on various pH ranges gels. Comparison of the 2DE pattern of proteins extracted from 386 and 386Mr confirmed the prediction that the vast majority of proteins were identical. The analysis focussed on identifying consistent differences in protein patterns between the isogenic lines in order to identify an alteration associated with Cymelarsan resistance.

The data presented provide evidence for a correlation between the absences of protein spot 2 (34 kDa, pI 4.5) and spot B (40 kDa, pI 5.8) on the 2D gels and the Cymelarsan resistance phenotype in *T. brucei* line 386. Protein spot 2 was identified as the gene product of a non-annotated ORF, and was named Cymelarsan Associated Resistance

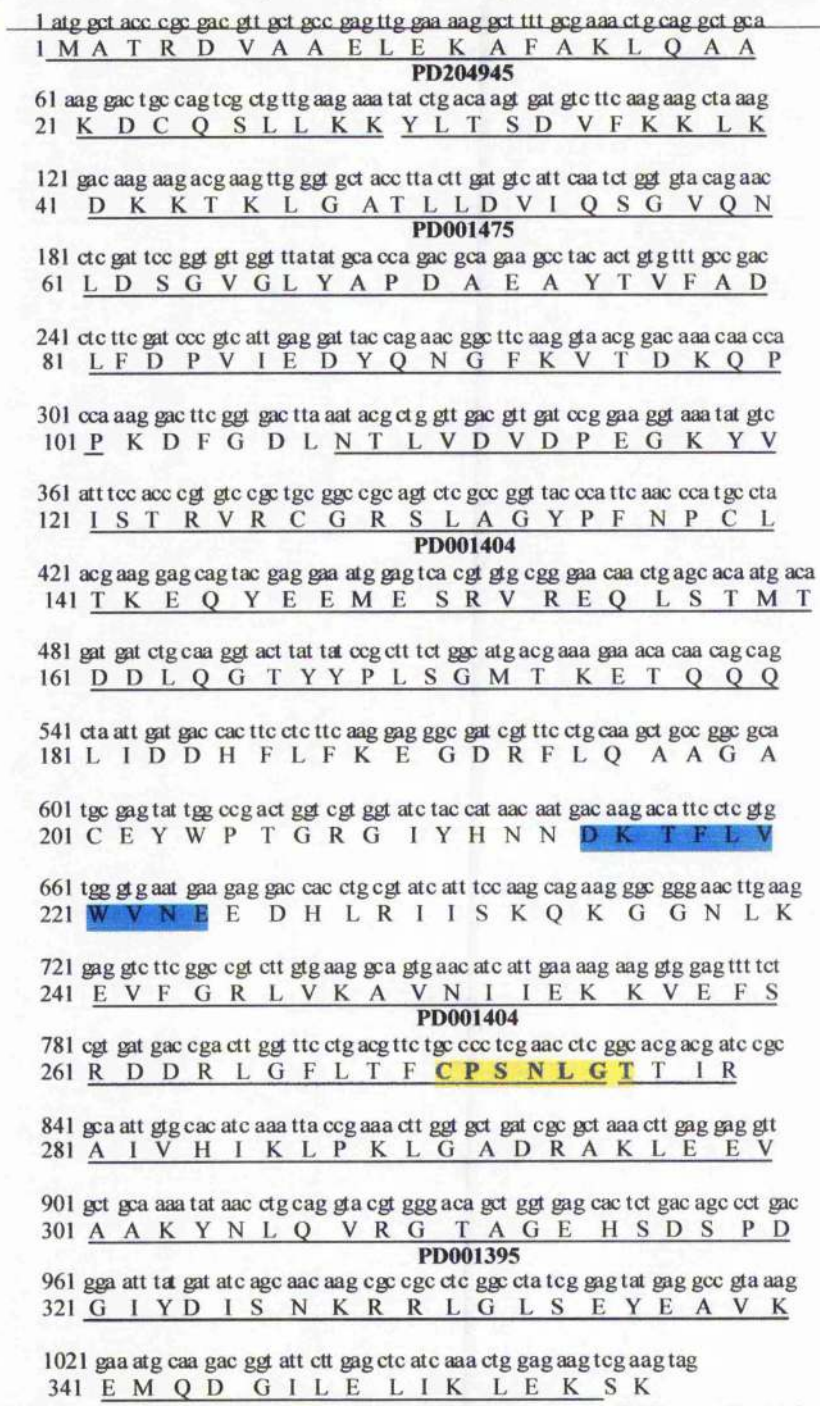

Figure 6.25: Schematic representation of the DNA and amino acid sequences of arginine kinase (ORF 345) from *T. brucei*. A signature sequence pattern of ATP:guanidine kinase (yellow) containing a reactive cysteine residue at position 271 was discovered and a putative actin binding domain (blue). Characteristic consensus sequences according to ProDom database are underlined.

Table 6.4: Information about the three genes encoding arginine kinase in *T. brucei*. The information was reproduced from GeneDB.

(CAR) protein and protein spot B was identified as an arginine kinase. The correlation between the absence of the CAR protein (spot 2) and Cymelarsan resistance was demonstrated on both broad and narrow pH range gels stained with the sensitive Sypro ruby dye and insensitive Coomassie brilliant blue stain.

Tandem MS analysis identified the CAR protein as matching ORF 274 on chromosome IX of *T. brucei*. The predicted pI calculated from the sequence of ORF 274 corresponded to the location of the CAR protein on the 2D gel. However, the predicted molecular weight (20.1 kDa) was lower than the observed molecular weight (34 kDa) of the CAR protein. This was also observed on SDS-PAGE gels for the recombinant gene product of ORF 274 produced for the antibody production. A Small Ubiquitin-related MOdifier (SUMO) protein attachment site was identified in the predicted sequence of the protein. Modification of the CAR protein by a SUMO protein would add 11 kDa to the molecular weight of the protein. The SUMO proteins are covalently conjugated onto lysine residues within target sequences. Most sumoylated proteins are nuclear, and three main functional roles of SUMO have been proposed: 1) protein targeting sumoylation has been shown to be important for nuclear import, 2) enhancement of protein stability, potential competition with (and inhibition of) ubiquitination and 3) transcriptional control (i.e. negative regulation of transcription from the androgen receptor) (Hay, 2001). The molecular weight of the recombinant gene product of ORF 274 produced in *E. coli*, for the generation of antibodies in mice was measured by mass spectrometry as 22 kDa, corresponding to 2 kDa higher than the expected molecular weight. The high molecular weight observed on SDS-PAGE and 2D gels is therefore not due to the attachment of a SUMO protein. An alternative explanation for the discrepancy in molecular weight is that the CAR protein is made of 16% of acidic residues (aspartate and glutamic acid). The high proportion of

negatively charged amino acids could account for the discrepancy between expected molecular weight and the apparent molecular weight of the CAR protein on 2D and SDS-PAGE gel. The location of arginine kinase on 2D gel corresponded to the predicted molecular weight and pI determined from the gene sequence of ORF 343 in GeneDB.

A BLAST analysis of GeneDB identified the presence of another copy of ORF 274 (Figure 6.26) and two more copies of the arginine kinase gene (Figure 6.27). The genes, encoding the CAR protein and spot 1, were present as tandem repeats on chromosome IX of reference line 927. As the sequences of the two ORFs are identical one would predict that the duplication had occurred recently. Duplication is important for genes whose functions are essential for the survival of the species (Gu *et al.*, 2003).

Two protein spots, which differed in isoelectric point on 2D gels of 386, were matched onto either ORF 274 or 277. As both ORFs have identical predicted amino acid sequences and no other homologues were found in the *T. brucei* genome, it is likely that the isoform is due to a post-translational modification. In principle, comparison of the mass spectrum of the modified protein with the unmodified protein should allow the identification of the modified peptide. However, the low sequence coverage obtained in Tandem MS for these protein spots meant that the identification of the modified peptide was not possible. In order to analyse reliably the differences, a higher quantity of protein would be required. This could now be achieved by immunoprecipitation using the antiserum to the expressed product of ORF 274.

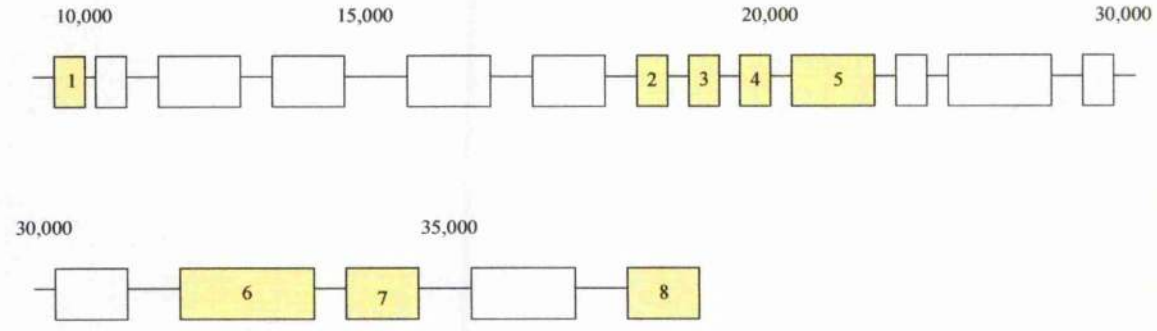

Figure 6.26: Representation of ORF 274 and 277 on chromosome IX of *T. brucei*. Complementary string of Chromosome IX (10 Kb to 35 Kb) with boxes indicating putative ORFs with homology to proteins in NCBI (yellow) or without homology to proteins in NCBI (white). Ubiquitin conjugating E2 enzyme (1), 60S ribosomal protein L10 (2), ORF 274 (3), ORF 277 (4), chaperone (5), cell cycle check point protein (6), metaloprotease like protein (7) and tyrosine phosphatase (8).

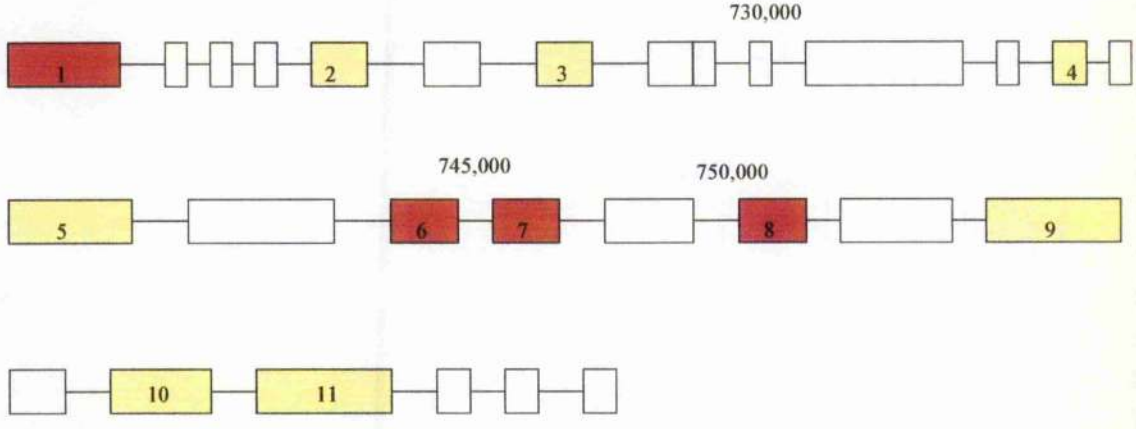

Figure 6.27: Representation of arginine kinase genes on chromosome IX of *T. brucei*. String of Chromosome IX (725 Kb to 760 Kb) with boxes indicating putative ORFs without homology to proteins in NCBI (white), putative ORFs with homology to protein in NCBI (yellow) and experimentally characterised ORFs (red). This region of the chromosome contains genes encoding glutamate dehydrogenase (1), NAD/FAD dependent dehydrogenase (2), 40s ribosomal protein S3 (3), calmodulin (4), phosphatase protein (4), conserved hypothetical protein (5), arginine kinase ORF 342 (6), arginine kinase ORF 343 (7), arginine kinase ORF 345 (8), ABC transporter (9), myo-inositol-1 phosphatase (10) and a transmembrane protein (11).

Sequence pattern searches on the predicted amino acid sequences of ORF 274 and arginine kinase revealed a number of possible modification sites, including potential phosphorylation and glycosylation sites (Figure 6.28). NetPhos predicted five threonines and two serines as putative phosphorylation sites on the gene product of ORF 274, and 14 putative phosphorylation sites on arginine kinase (ORF 342). The protein spots from the 2D gel were identified by mass spectrometry. Because post-translational modification causes a peptide mass shift, any peptide found to match onto the protein can be considered free from modification. This reduced the potential modification sites present on the gene product of ORF 274 and arginine kinase to 5 and 10 phosphorylation sites respectively (Figure 6.28). Protein phosphorylation can be involved in the activation/inactivation of enzyme activity, modulation of molecular interactions and signalling. For example, activation of a kinase by protein phosphorylation is a hallmark of intracellular signalling cascades (Hunter, 1995). Potential post-translational regulation of the gene product of ORF 274 and 277 could allow large amounts of the protein and enzyme to be present in the cell in an inactive form.

InterPro and Pfam searches revealed the presence of a nascent polypeptide associated complex (α NAC domain) at the N terminal and an ubiquitin associated domain (UBA domain) at the C terminal of the gene product of ORF 274. In humans, NAC is a heterodimeric complex of two subunits: α NAC of 33 kDa and β NAC of 21 kDa. Similarly, α (Egd2p) and β (Egd1p) subunits have been found in yeast (Shi *et al.*, 1995). The mammalian NAC complex acts in the regulation of co-translational transport of proteins into the endoplasmic reticulum, and was also shown to be involved in transcriptional regulation. In yeast however, the NAC complex has a different function as it binds ribosomes, protecting newly synthesized polypeptide chains from degradation and

Figure 6.28: Predicted post-translational modification sites on gene product of ORF 274 (A) and arginine kinase (B). Potential threonine and serine phosphorylation sites (yellow), as predicted by NetPhos (http://www.cbs.dtu.dk/services/NetPhos), N-glycosylation site (blue) as predicted by NetNGlyc (http://www.cbs.dtu.dk/services/NetNGlyc), and SUMO protein attachment site (red) as predicted by Abgent (http://www.abgent.com/cgi-bin/tools.pl) are shown on the amino acid sequence. No myristoylation (http://mendel.imp.univie.ac.at/myristate/SUPLpredictor.htm) or sulfination sites (http://us.expasy.org/cgi-bin/sulfinator.pl) were found. The sequences underlined correspond to the matching peptide fragmented by Tandem MS from spot 2 and spot B.

preventing any inappropriate translocation into the reticulum (Wang *et al.*, 1995). The role of such domains in *T. brucei* remains to be elucidated.

The UBA domain was first identified in 1996 in proteins that function in ubiquitin mediated proteolysis (Hofmann and Bucher, 1996). Since then this domain has been found in proteins that lack any obvious link to proteolysis. The structure and function of the UBA domain has been mainly studied in humans and yeast. The UBA domain is composed of 35 amino acid residues which form a sequence motif containing three alpha helices (Figure 6.29). Structure analysis of various UBA containing proteins suggest that conserved residues contribute to the common structure of the UBA domain, while divergent residues on the surface of the helices would permit the selective interaction with different protein targets. Target proteins include ubiquitin, multi-ubiquitin chains, ubiquitinated proteins and other effectors, predicting a role for this motif in protein-protein interaction and subcellular targeting (Wilkinson *et al.*, 2001; Mueller and Feigon, 2002; Hofmann and Bucher, 1996). The association of the NAC and UBA domains in a protein is not uncommon, as shown in yeast with Egdp2 (Shi *et al.*, 1995; Wang *et al.*, 1995). The association of the two domains in one protein could indicate that the function of this protein is in the degradation or refolding of newly synthesised proteins with folding defects.

Arginine kinase belongs to a family of conserved proteins with phosphotransferase activity, the guanidine kinases. Arginine kinase catalyse the synthesis of N-phosphorylated guanidine compounds by the reversible transfer of a phosphoryl group from ATP to an enzyme-specific guanidine acceptor. Phosphoarginine, the reaction product, plays a crucial role as an energy reserve because the high-energy phosphate can be transferred when a

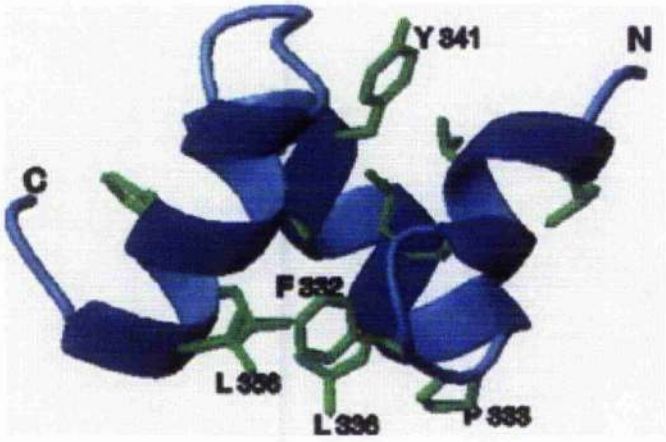

Figure 6.29: **UBA domain structure**. Ribbon representation of the structure of a human DNA repair protein UBA domain as determined by NMR spectroscopy. The representation sows the characteristic compact three-helix bundle encoded by the conserved residues of all UBA domains (reproduced from Dieckmann *et al.*, 1998).

renewal of ATP is needed. ATP consumption and high energy phosphate regeneration are required to support processes such as stage differentiation, cell division and motility. Phosphoarginine is presumed to support rapid bursts of cellular activity in the short term until metabolic pathways such as glycogenolysis, glycolysis and oxidative phosphorylation are switched on (Hird and McLean, 1986). Arginine kinase has been identified in *T. brucei* (Pereira *et al.*, 2002) and *T. cruzi* (Pereira *et al.*, 2000; Pereira *et al.*, 1999). These gene sequences contain all the characteristic consensus blocks of the guanidino kinase family and a putative actin-binding domain (Pereira *et al.*, 2000).

The results presented in this chapter suggest that the absence of the CAR protein, an isoform of spot 1, is associated with Cymelarsan resistance in *T. brucei*. The question arises as to whether the change in CAR expression is a general feature of Cymelarsan resistance in *T. brucei* or is a particular attribute of the 386Mr line only. A proteomic analysis of a second pair of isogenic lines of Cymelarsan resistant and sensitive *T. brucei* lines has been undertaken and the results are presented in the next chapter.

Chapter VII

Association of the CAR protein and Cymelarsan resistance in line 247 and 927

7.1 Introduction

The proteomic study performed on the pair of isogenic lines of 386 demonstrated a positive correlation between the absence of the CAR protein (located at pH 4.5, 34 kDa) with resistance to Cymelarsan in *T. brucei* (chapter 6). The CAR protein and its isoforms are encoded by two ORF's present as a tandem repeat on chromosome IX. Analysis of these ORFs in the 386 and 386Mr lines demonstrated the absence of sequence differences between the ORFs that could account for the presence of the CAR protein isoform of spot 1, in the sensitive 386 line. In addition, both ORFs were transcribed in both isogenic 386 lines. Consequently, it was suggested that the presence of three protein spots encoded by ORF 274 and 277 (one of which being the CAR protein spot) in the sensitive line was due to a post-translational modification, and that the protein spots encoded by ORF 274 and 277 in the resistant line is not modified.

The question arises as to whether the change in CAR protein expression is a general feature of Cymelarsan resistance or is a particular attribute of the 386Mr line only. To address this question a 2DE analysis was undertaken with of a second pair of isogenic lines of Cymelarsan sensitive and resistant lines of 247. The Cymelarsan resistant line of 247 was generated from the sensitive 247 line *in-vivo* by increasing sub-curative doses of Cymelarsan (Scott *et al.*, 1996). This line was produced following the same protocol as the 368 isogenic lines.

Resistance to Cymelarsan in the procyclic form of the laboratory induced resistant line of 247 was shown to be 1,257 fold greater than in the parental line (chapter 5).

Proteins from Cymelarsan sensitive and resistant 247 lines were separated by 2DE and analysed by Tandem MS. Subtractive analysis of the region of the gel at pH 4.5 and 34 kDa was undertaken. Western blot analysis using antibodies raised against the transcriptional product of ORF 274 was performed on 2D gels to analyse the CAR protein spot and its isoforms in 247 and 247Mr lines. In addition, a 2DE analysis of the genome reference line 927 was undertaken. In each case, the analysis was focussed on expression of transcriptional products of ORF 274 and 277 rather than undertaking a general proteome scan.

7.2 Materials and Methods

7.2.1 *In vitro* culture of procyclic trypanosomes

Procyclic forms of the three lines were grown *in-vitro* in complete SDM79 as described in chapter 2.

7.2.2 Protein extraction, 2DE and mass spectrometry

Whole soluble protein extract was obtained from $1x10^8$ procyclic forms of trypanosomes using protocol P2 as described in chapter 2. Fresh protein extracts were made for each gel as proteins from the 247 lines seemed to degrade when stored at -20°C (data not shown).
The whole soluble protein extract was separated by 2DE on pH 4-7 gels as described in chapter 6. The gels were stained with either Sypro orange or colloidal Coomassie blue stain.

For Sypro orange staining, the gels were fixed overnight in a solution of 7.5% acetic acid and 10% methanol. The gels were incubated in 0.005% SDS for 1 h and then transferred in the Sypro orange dye diluted (1/5,000) in 7.5% acetic acid in which they were left overnight. Gels were rinsed briefly in a solution of 7.5% acetic acid and 30% methanol, and images were acquired immediately with the Typhoon scanner as previously described (chapter 2) using the green laser.

For colloidal Coomassie blue staining, the gel was fixed for 3 h in a solution of acetic acid (10%) and ethanol (40%). The gel was washed twice in water for 10 min before being transferred into the colloidal Coomassie blue stain (1 part methanol/1 part colloidal stock (50 g ammonium sulphate, 6 ml ortho-phosphoric acid, 500 ml ddH_2O, 10 ml of a 5% Coomassie blue G 250 solution)). The gel was left to stain for three days. The gel images were acquired as described in chapter 2.

Protein spots of interest were excised from the gel and digested with trypsin using the in-gel protein digestion protocol described in chapter 3. Tandem MS analysis of the proteins was performed as described in chapter 4.

7.2.3 SDS-PAGE gels and Western blot analysis

SDS PAGE gels and Western blot analysis were performed as described in chapter 6.

7.3 Results

7.3.1 Proteomic analysis of the isogenic 247 lines

Proteins from the isogenic lines of 247 were extracted and separated by 2DE on pH 4-7 gels to detect the CAR protein spot and its isoforms in 247 and 247Mr lines. Tandem mass

spectrometry was performed to identify the protein spots located at and around the expected location of the CAR protein on the 2D gels. The gels were stained with Sypro orange. Analysis of the gels using the ImageMaster 2DElite showed 363 proteins spots on the gel from the 247 line and 388 protein spots on the gel from the 247Mr line. The general 2D pattern of proteins from the 247 and 247Mr lines was very similar, as expected from isogenic lines (Figure 7.1). In addition, comparison of the gels from the two pairs of isogenic lines (386 and 247) revealed a high similarity in 2D pattern on pH 4-7 gels. Comparison of the 2D pattern in the area of the gel at approximately 34 kDa and pH 4.5 between 247 and 247Mr lines showed no differentially expressed protein spots. Protein spots located in this area were excised from the gels, digested with trypsin and analysed by Tandem MS. Protein spots 1, 3 and 4 from the sensitive line 2D gel and 1, 2, 3, and 4 from the resistant line 2D gel were identified with high confidence as β tubulins (Figure 7.2). β tubulins had previously been found to surround the CAR protein spots on 2D gels from the isogenic lines of 386 (chapter 6). The identification of these spots demonstrated that the location on the gels from the 247 lines corresponded to the location of the CAR protein spots on gels from the 386 lines. No protein spots were detected at the expected location of the CAR protein spots on the gels from 247 and 247Mr (Figure 7.1).

7.3.2 Presence of ORF 274 and 277 in isogenic 247 lines

Since the CAR protein spot and its isoforms could not be visualised on 2D gels of 247 and 247Mr lines at the expected location, the question arises as to whether the ORFs encoding the CAR protein exist in the 247 genome. To address this question, a PCR was performed on genomic DNA of lines 247 and 247Mr using ORF specific primers (274F/274R, 277F/277R). PCR products of the expected size were observed for both ORF 274 and 277 in 247 and 247Mr lines (Figure 7.3). In addition, a smaller PCR product was also amplified using these

Figure 7.2: Tandem mass spectrometry analysis of protein spots located in the expected region of the CAR protein. Location of the protein spots from 247 (A) and 247Mr (B) lines. The table (C) gives a summary of the results obtained searching the NCBInr database using the MASCOT® search engine with the mass spectra acquired. The empty circles indicate the expected position of the CAR protein spot and its isoform.

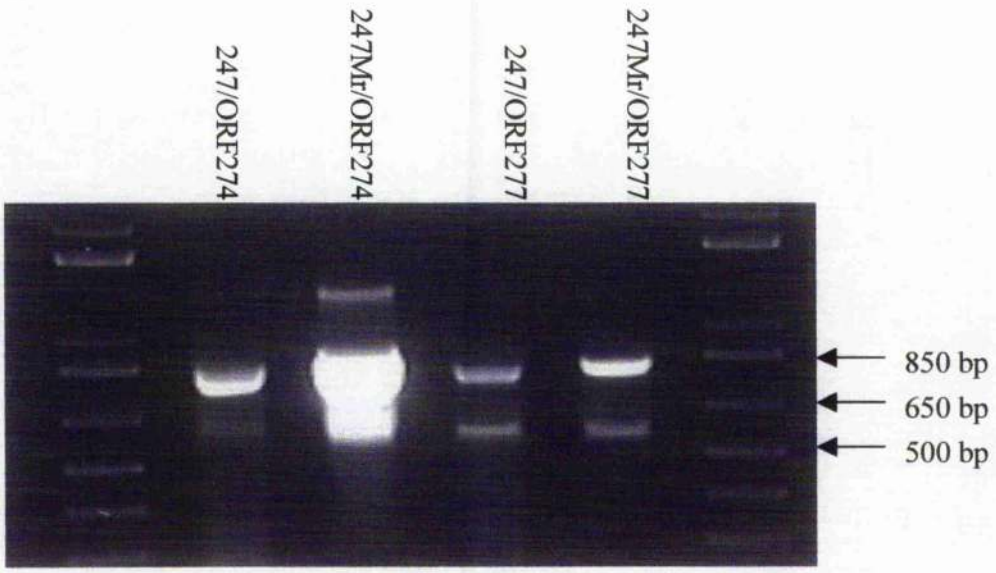

Figure 7.3: **PCR amplification of ORF 274 and 277 from isogenic 247 lines.** The PCR was performed using the ORF specific primers. The main product corresponded to the expected size for each ORF (ORF 274 = 891 bp, ORF 277 = 868 bp).

primers. This smaller product was not recovered from PCR amplification of genomic DNA from the 927, 386 and 386Mr lines.

These results would suggest that the pair of isogenic 247 lines both contain ORF 274 and 277 in their genome.

7.3.3 Presence of expressed product of ORF 274 and 277 in isogenic 247 lines

The CAR protein spot and its isoform could not be detected on 2D gels of 247 and 247Mr lines at its expected location. However, ORF 274 and 277, encoding the CAR protein, were shown to be present in each line. In view of these results a Western blot analysis of whole cell extract separated by SDS-PAGE gel was performed. This analysis revealed the presence of ORF 274 protein in both lines (Figure 7.4). The protein detected had a similar molecular weight to the recombinant His tagged transcriptional product of ORF 274 (34 kDa). Higher molecular weight bands were also detected in the lane containing purified recombinant His tagged protein. These probably correspond to dimers and trimers of the transcriptional product of ORF 274, however no molecular weight marker was run on the gel so the size cannot be determined.

To assess the number of CAR protein isoforms and their pIs in 247 and 247 Mr lines, 2D gels of these lines were run and Western blotted. Only one transcriptional product of ORF 274 could be detected at 34 kDa, pH 4.5 for both 247 and 247Mr lines (Figure 7.5). Other products were detected at lower molecular weight and basic pH in both 247 and 247Mr lines. These fainter spots might correspond to degradation products or could indicate a cross-specificity

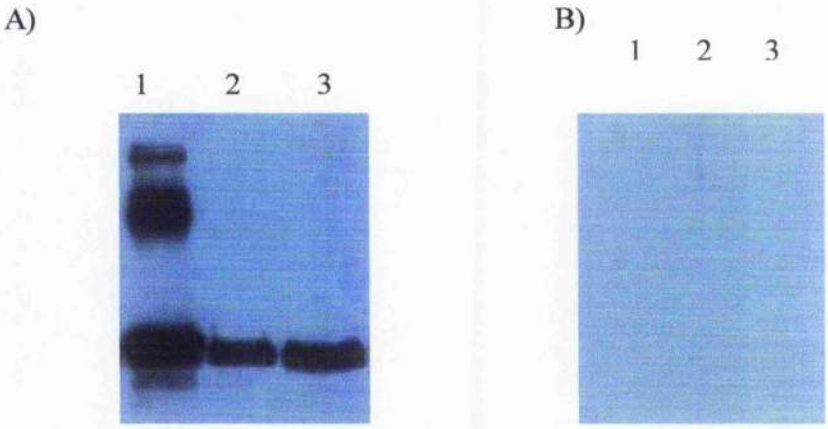

Figure 7.4: Western blot analysis of expression of the gene product of ORF 274 in the isogenic 247 lines. Protein extracts from 247 (lane 2) and 247Mr (lane 3) were separated by SDS-PAGE gels and electro-transferred onto a nitrocellulose membrane. The membrane was blotted with mouse anti-CAR antibody and detected with HRP-conjugated anti-mouse IgG (1/1000) and the ECL detection kit. The positive control was the His-tagged recombinant CAR protein (lane 1).
Serum from non-immunised mice was used as negative control (B).

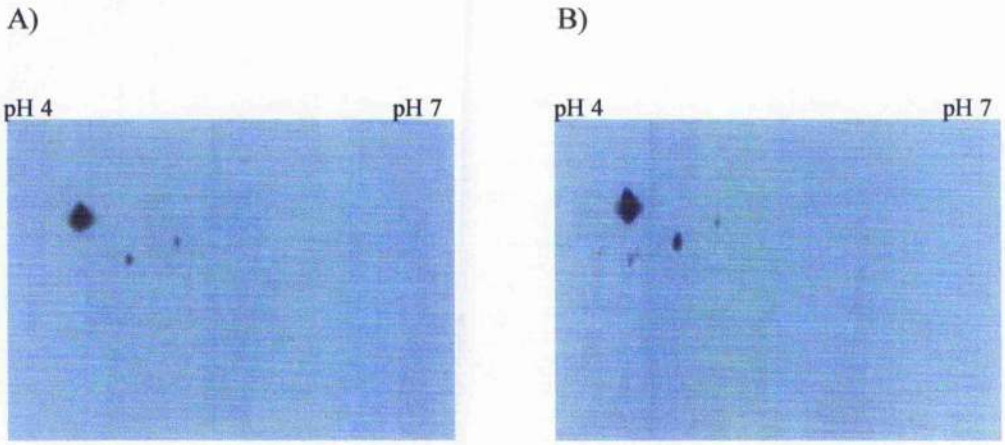

Figure 7.5: Western blot analysis of expression of isoforms of the gene product of ORF 274 in isogenic 247 lines. Cymelarsan sensitive (A) and resistant (B) 247 lines.

of the antiserum to another protein not detected on one dimensional SDS-PAGE gels.

7.3.4 Proteomic analysis of line 927

Protein extracted from procyclic forms of line 927 were separated by 2DE on pH 4-7 gel and stained with colloidal Coomassie blue. I am grateful to Anne Fladas for running and staining the gel. Examination of the 2D gel revealed a similar general 2D pattern of protein spots at location of 34 kDa and pH 4.5 as lines of 386 and 247. A protein spot located on the 2D gel at the expected position of a CAR protein isoform was detected. This spot (spot 6) was excised from the gel, digested with trypsin and analysed by Tandem MS. The MASCOT[40] search engine was used to search the NCBInr and the local *T. brucei* database. The protein spot matched onto ORF 274 encoding the CAR protein with a score of 95, indicating an correct identification within 95% confidence limits (Figure 7.6).

These results would suggest that only one isoform of the CAR protein was present in line 927 at a location of 34 kDa and pH 4.5.

7.4 Discussion

The presence of the CAR protein spot and its isoform in *T. brucei* isogenic Cymelarsan sensitive and resistant 247 lines and the genome reference 927 line was assessed by 2DE analysis and Western blot analysis as the absence of the CAR protein was associated with resistance to Cymelarsan in the 386 lines.

No protein spot could be detected by Sypro orange staining at the expected location on the CAR protein spot and its isoforms in 247 and 247Mr. However, a single protein product of ORF 274 was detected by Western blot analysis of 2D gels at the expected location for both Cymelarsan sensitive and resistant 247 lines. This suggests that the quantity of protein of ORF 274/277 expressed in the 247 lines is lower than the sensitivity of the Sypro orange stain, or alternatively that it doesn't stain with Sypro orange. In addition, these results suggest that in the isogenic 247 lines the transcriptional product of ORF 274 and 277 was perhaps expressed at a lower level than in 386 lines where the CAR protein is readily detectable by Coomassie Brilliant blue.

Only one transcriptional product of ORF 274 and 277 was detected at pH 4.5, 34 kDa in both 247 and 247Mr lines, suggesting that the CAR protein is not associated with Cymelarsan resistance in this pair of *T. brucei* isogenic lines.

A possible clue to the mechanism of Cymelarsan resistance in *T. brucei* is the diminished metabolism of the Alamar Blue dye in the 386Mr and 247Mr (chapter 5). This new phenotype associated with cymelarsan resistance in the two pairs of isogenic lines will be further investigated in the next chapter.

Chapter VIII

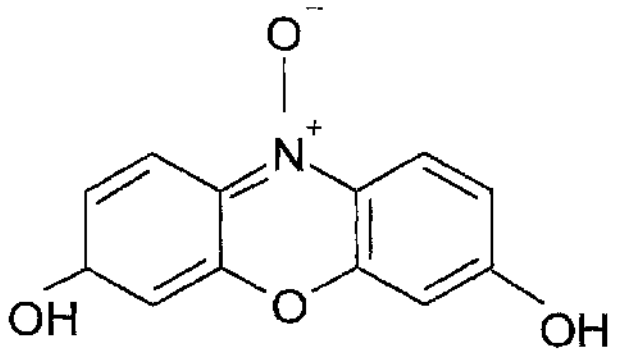
The Alamar Blue phenotype

8.1 Introduction

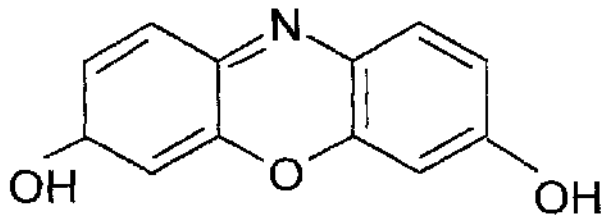
The use of the Alamar Blue dye in *in vitro* assays for testing sensitivity of cells to drugs is based on the ability of intracellular enzymes to reduce the non-fluorescent blue dye to a pink fluorescent compound (Figure 8.1). The reduction of the dye correlates with growth and metabolic activity of the cells in the presence/absence of drug, and can be measured by spectrofluorometry and spectrometry. The Alamar Blue assay was recently developed as an *in-vitro* assay to test drug sensitivity/resistance of procyclic trypanosomes in culture (Räz *et al.*, 1997). The assay was shown to be simple, fast, reproducible and economical.

The assay performed in the absence of drug on procyclic stages of each pair of isogenic lines, demonstrated a marked difference in the level of reduction of the Alamar Blue dye between the Cymelarsan sensitive and resistant lines as shown in chapter 5. In the presence of increasing concentrations of Cymelarsan, the sensitive lines (247 and 386) showed a dose dependent response with a decrease in fluorescence from Alamar Blue as the trypanosomes viability is lost. In contrast, the two resistant lines (386Mr and 247Mr) showed no change in the level of Alamar Blue fluorescence with increasing levels of Cymelarsan (0.001 μM to 1,000 μM).

A)



B)



C)

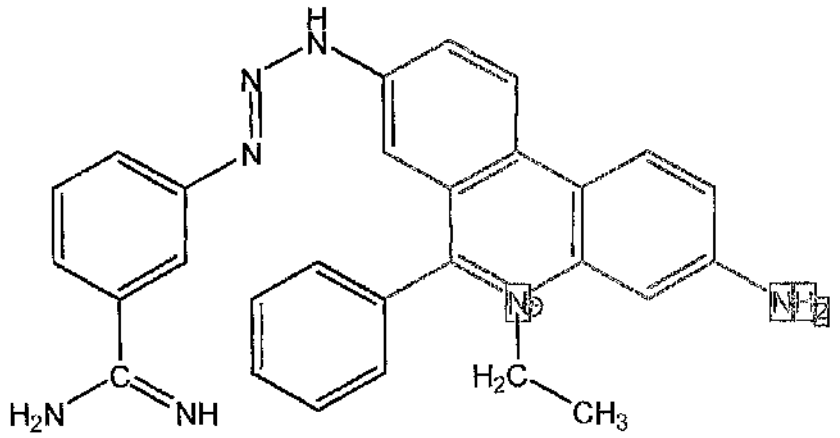


Figure 8.1: **Structure of the Alamar Blue dye and the Isometamidium.** The reduced form of the Alamar Blue dye (B) is fluorescent and can be detected by spectrofluorometry or spectrometry. The structural similarities between the oxidized Alamar Blue structure (A) and Isometamidium (C) are highlighted in blue. The structure of Isometamidium correspond to the active form (red isoform) of the drug found in Samorin®.

The fluorescence from the Alamar Blue dye produced by the Cymelarsan resistant lines was almost constant whether the trypanosomes were alive or dead. However, the fluorescence from the Alamar Blue dye was higher in the presence of Cymelarsan resistant lines than without trypanosomes in the medium, demonstrating some reduction of the Alamar Blue dye by the trypanosomes (chapter 5). The decrease ability to reduce Alamar Blue shown by the Cymelarsan resistant lines demonstrated an unexpected association of the Alamar Blue phenotype with Cymelarsan resistance.

This new phenotype associated with Cymelarsan resistance might potentially be linked to the mechanism of Cymelarsan resistance in *T. brucei*. In this chapter, an attempt is made to identify the mechanism that impaired the reduction of the Alamar Blue dye in the Cymelarsan resistant lines. The Alamar Blue dye can only be reduced by intracellular enzymes (O'Brien *et al.*, 2000), therefore two possible mechanisms of decrease in reduction of Alamar Blue were tested: the presence and activity of reductive enzymes in the lines and the transport/export of the Alamar Blue dye into/from the trypanosomes.

To test for the presence and activity of reductive enzymes, the following question was addressed:

1- is there any difference in cell lysate reductive activity of Alamar Blue between the sensitive and resistant lines?

To test whether and how the Alamar Blue dye was taken up by trypanosomes, the following questions were addressed:

1- What are the effect of P-glycoprotein inhibitors on the reduction of the Alamar Blue dye?

2- What is the activity of the transporter for Isometamidium, which possess a common structure with the Alamar Blue dye?

3- What are the actions of chloroquine and other lysosomotropic agents on the reduction of the Alamar Blue dye?

4- What is the localisation of the reduced Alamar Blue due inside trypanosomes?

8.2 Materials and Methods

8.2.1 Commonly used reagents

Ammonium chloride, Bafilomycin A1, Concanamycin A, chloroquine, verapamil, PCP, TFP were purchased from SIGMA. LS 55 Luminescence Spectrometer was from Perkin Elmer instruments. The fluorescent microscope and camera were purchased from Zeiss. Samorin® was purchased from May and Baker (UK). Alamar Blue was purchased from Trek Diagnostic System, Inc. and Cymelarsan was a kind gift from Rhône Merieux. Chloroquine was a gift from Dr Lisa Ranford-Cartwright (University of Glasgow).

8.2.2 *In vitro* culture of procyclic trypanosomes and cell lysate preparation

Procyclic stages of each pair of isogenic lines were grown *in vitro* in complete SDM79 as described in chapter 2.

Cell lysates were prepared in PBS in the presence of protease inhibitor cocktail and nucleases as described in chapter 2. The protein concentration from the cell lysate was determined using a Coomassie Plus Protein Assay (Pierce) according to the manufacturer's instructions, using bovine serum albumin as the protein standard.

8.2.3 *In vitro* drug sensitivity testing

8.2.3.1 The Alamar Blue assay

The Alamar Blue assay was performed on procyclic cultures of the two pairs of isogenic lines (386/386Mr and 247/247Mr) as described in chapter 5.

Doubling serial dilutions of test compounds (P-glycoprotein inhibitors, chloroquine, Bafilomycin A1, Concanamycin A and ammonium chloride) in complete SDM79 were set out in a 96 well plate in duplicate, in a volume of 100 µl (Table 8.1). 100 µl of trypanosome culture ($2x10^6$ trypanosome/ml) were added to each well, with 20 µl of the Alamar Blue dye. Measurements with a LS 55 Luminescence Spectrometer were taken, after 24 h incubation at 25°C, as described in chapter 5. Each experiment was performed in duplicate and replicated at least once. The presence and viability of the trypanosomes in each well was confirmed by microscopy.

The Alamar Blue assay was also performed directly on cell lysates from each pair of the isogenic lines. In the first experiment, the cell lysate (100 µl) and Alamar Blue dye (10 µl) were mixed to assess the level of reduction of the dye by the intracellular enzymes from Cymelarsan sensitive and resistant lines of 386 and 247. The measurements were taken after incubation for 24 h at 25°C. In the second experiment, the assay was performed in the presence of doubling serial dilutions of chloroquine in PBS to assess the action of chloroquine on the intracellular enzymes. 100 µl of chloroquine (0.005 to 50 µM) was mixed with cell lysate (100 µl) and Alamar Blue dye (20 µl), incubated for 24 h at 25 °C and the reduction of

		Final concentration	
Inhibitor	**Compound**	**Minimum**	**Maximum**

	PCP	0.01 mM	1 mM
	TFP	0.01 mM	1 mM
Inhibitor of proton pump	Chloroquine	5 μM	50 μM
	Bafilomycin A1	0.001 μM	32 μM
	Concanamycin A	0.01 μM	29 μM
	Ammonium chloride	0.01 mM	1 M

Table 8.1: Concentrations of test compounds used in the Alamar Blue assay.

the Alamar Blue dye was recorded using a LS 55 Luminescence Spectrometer as described in chapter 5. The experiment was performed in duplicate and repeated at least once.

8.2.3.2 Growth inhibition assay

To assess for the relationship between the decrease in fluorescence of the Alamar Blue dye and resistance to the trypanocidal drug Isometamidium, an *in vitro* growth inhibition assay was performed as previously described in chapter 5. The drug was serially diluted in complete SDM79 with final concentrations ranging from 0.001 μM to 1,000 μM. The percentage inhibition is expressed relative to the cell densities in cultures growing in the absence of Isometamidium. The experiment was carried out in triplicate and was repeated at least three times on each pair of the isogenic lines.

8.2.4 Fluorescence microscopy

The localisation of the reduced Alamar Blue dye and Isometamidium in procyclic stages of each pair of the isogenic trypanosomes were investigated by fluorescence microscopy using the intrinsic fluorescence of these compounds.

The localisation of the Alamar Blue dye in procyclic trypanosomes was observed by adding 20 μl of the Alamar Blue dye to 200 μl of procyclic cultures. After incubating for 1 min at room temperature, 5 μl of live trypanosomes were placed on a slide and covered with a coverslip. Cells were immediately examined on a Zeiss UV microscope (Axiovert 200M) fitted with a DAPI filter, and images taken with a camera (AxioCam) using Axiovision software, version 3.0 (Zeiss). Trypanosomes were also observed under phase contrast to assess the morphological integrity of the cells.

To assess for the effect of chloroquine on the localisation of the Alamar Blue dye inside the trypanosomes, chloroquine was mixed with the Alamar Blue dye in SDM79 at a concentration of 50 μM, and added to procyclic trypanosomes of each pair of isogenic lines. The mixture was immediately placed on a slide, covered with a coverslip and viewed using a DAPI filter and phase contrast microscopy as previously described.

Procyclic stages of the isogenic lines (10 μl at $6x10^6$ trypanosome/ml) were mixed with 10 μM Isometamidium (10 μl) in SDM79. The presence of the Isometamidium drug inside each pair of isogenic lines was assessed by fluorescence microscopy as previously described. The viability and morphological integrity of the cells were assessed by phase contrast microscopy.

8.3 Results

8.3.1 Enzymatic reduction of the Alamar Blue dye

To test whether the difference in the level of reduced Alamar Blue dye produced by Cymelarsan sensitive and resistant lines was due to a defect in the ability of the parasite's intracellular enzyme to metabolise the Alamar Blue dye, Alamar Blue assays were performed on cell lysate from each pair of isogenic lines. The fluorescence, recorded at 590 nm, showed no detectable difference in the level of reduction of the Alamar Blue dye between cell lysates from Cymelarsan sensitive and resistant lines for both pairs of isogenic lines, as compared to the difference in fluorescence observed for live trypanosomes (Table 8.2).

	Line	Average protein concentration (mg/ml)	Average optical density (at 530 nm)	Ratio: optical density/concentration
	Control	0	25.42	-
Cell lysate	386	2.98	276.06	92.63
	386Mr	2.58	217.08	84.14
	247	3.40	395.58	116.34
	247Mr	3.40	326.35	95.98
Procyclic trypanosome	386	-	251.16	-
	386Mr	-	177.08	-
	247	-	219.53	-
	247Mr	-	123.97	-

Table 8.2: *In vitro* Alamar Blue assays on cell lysates from the two pairs of isogenic lines. The cell lysates were prepared in PBS and the control consisted of PBS only. The optical density obtained for procyclic trypanosomes ($4x10^6$ trypanosome/ml) was added in the table for comparison of Alamar blue reduction from live trypanosome and cell lysates.

These results would suggest that both Cymelarsan sensitive and resistant lines possess the enzymes able to reduce the Alamar Blue dye, and that the enzymes are active in both Cymelarsan sensitive and resistant lines.

8.3.2 Assessment of the efflux of the Alamar Blue dye by P-glycoprotein

Efflux of drugs through a membrane protein, P-glycoprotein, has been reported as a mechanism of drug resistance in *T. cruzi* (Neal *et al.*, 1989) and *T. congolense* (Sutherland and Holmes, 1993). An increased efflux of the Alamar Blue dye could explain the decreased fluorescence produced by the Cymelarsan resistant lines. To assess this hypothesis the Alamar Blue assay was performed in the presence of three general inhibitors of P-glycoproteins (verapamil, PCP and TFP) on each pair of isogenic lines. These three compounds have been reported to revert drug resistance by inhibition of P-glycoproteins at concentrations of 5 μM for TFP and PCP and 15 μM verapamil in Leishmania (Basselin *et al.*, 2002) and 8 μM for verapamil in *T. cruzi* (Neal *et al.*, 1989). For both pairs of isogenic lines, verapamil, PCP and TFP were lethal to trypanosomes at concentrations of 1 mM, 0.1 mM and 0.1 mM respectively as assessed by microscopic examination of the cultures. At non-lethal concentrations, the presence of the P-glycoprotein inhibitors had no effect on the level of reduced Alamar Blue dye produced by the 386Mr and 247Mr after 24 h exposure (Figure 8.2 and 8.3). Similarly, the level of reduced Alamar Blue dye produced by the 386 and 247 lines was not altered by the presence of P-glycoprotein inhibitors at sub-lethal doses. These results suggest that the low level of fluorescence obtained from the reduction of the Alamar Blue dye observed in Cymelarsan resistant lines is not associated with an increased efflux of the dye by an over-expressed P-glycoprotein.

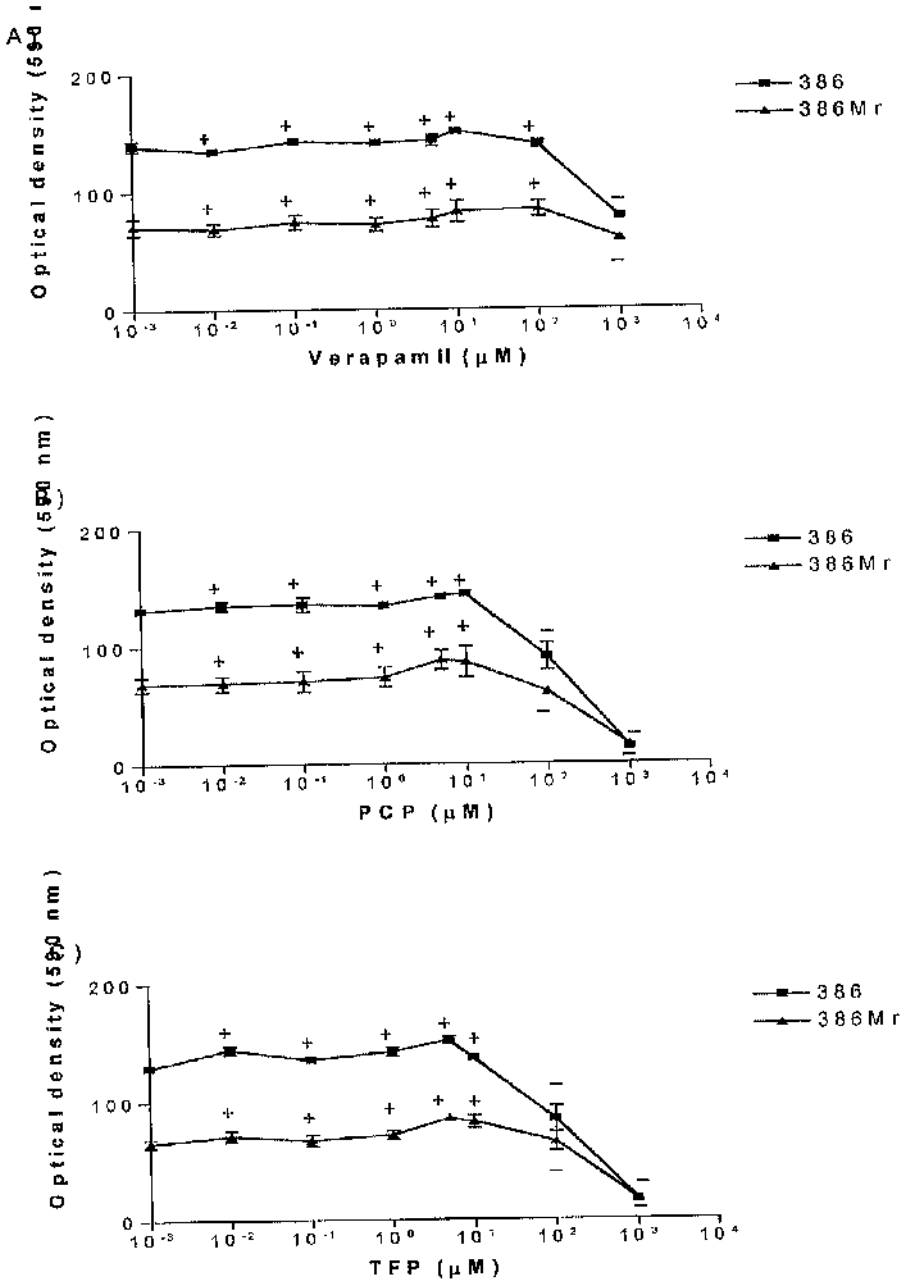

Figure 8.2: Alamar Blue assays in the presence of P-glycoprotein inhibitors for the isogenic lines of 386. Procyclic forms were incubated in the presence of the Alamar Blue dye and three common P-glycoprotein inhibitors, verapamil (A), prochlorperazine (PCP, B) and trifluoperazine (TFP, C) in SDM 79. The status of the procyclic culture is indicated for each concentration of inhibitors as alive (+) or dead (-) as assessed by microscopy. The lowest concentration corresponds to the control in the absence of drug. The error bars represent the mean +/- SEM, n = 4.

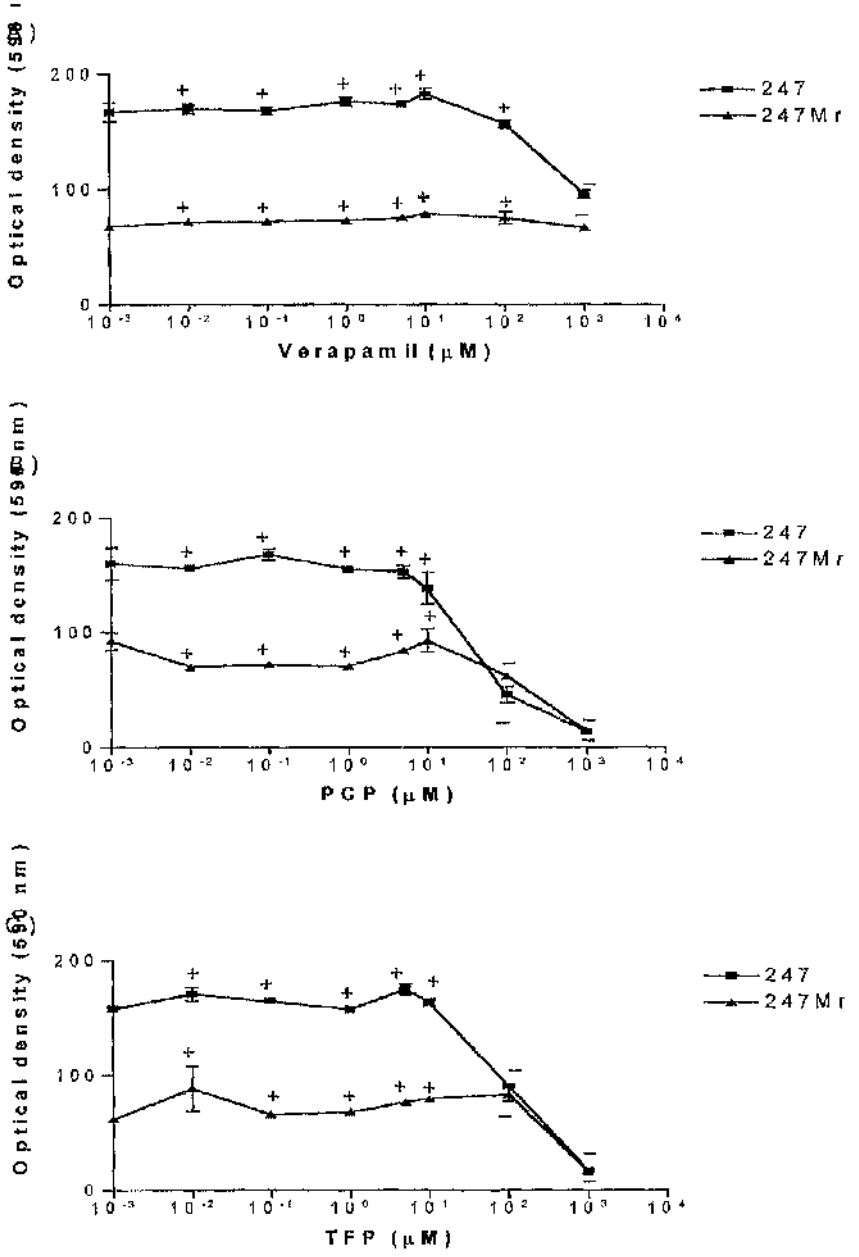

Figure 8.3: Alamar Blue assays in the presence of P-glycoprotein inhibitors for the isogenic lines of 247. Procyclic forms were incubated in the presence of the Alamar Blue and three common P-glycoprotein inhibitors, verapamil (A), prochlorperazine (PCP, B) and trifluoperazine (TFP, C) in SDM79. The status of the procyclic culture is indicated for each concentration of inhibitors as alive (+) or dead (-) as assessed by microscopy. The lowest concentration corresponds to the control in the absence of drug. The error bars represent the mean +/- SEM, n = 4.

8.3.3 Mode of transport of the Alamar Blue dye

8.3.3.1 A possible transporter for the Alamar Blue dye

Isometamidium is a trypanocidal drug structurally similar to the Alamar Blue dye (Figure 8.1). It possesses the same three phenyl ring structure, a positively charged quaternary ammonium in the same position on the ring, and a NH_2 group (corresponding to a OH group in the Alamar Blue dye) able to form a hydrogen bond (Figure 8.1). These structural similarities could imply an uptake of the Alamar Blue dye mediated via the same transporter that is used by Isometamidium (de Koning, personal communication). To test whether there was a defect in the Isometamidium transporter in the two Cymelarsan resistant lines that could be linked to the decrease level of reduced Alamar Blue dye produced, a growth inhibition assay was performed on isogenic lines of 386 and 247 in the presence of Isometamidium. Isometamidium is a naturally fluorescent drug which stains the nucleus and the kinetoplast of trypanosomes. This characteristic was also used to assess the uptake of Isometamidium into the trypanosomes.

In vitro growth inhibition assays of procyclic stages of each pair of isogenic lines were performed in the presence of serially diluted Isometamidium in SDM79. Both Cymelarsan sensitive and resistant lines exhibited a dose-dependent response to the drug. No detectable differences in dose-dependent inhibition were observed between sensitive and resistant lines for both pairs of isogenic lines (Figure 8.4A and 8.5A). Fluorescence microscopy of the procyclic forms of the isogenic lines incubated in 10 μM of Isometamidium using the DAPI filter showed the staining of the kinetoplast by the drug (Figure 8.4C and 8.5C). The stained

kinetoplast was detectable in both Cymelarsan sensitive and resistant lines, demonstrating the occurrence of Isometamidium uptake. The pairs of isogenic lines were also observed under phase contrast (Figure 8.4B and 8.5B) to assess the morphological integrity of the trypanosomes. These results suggest that a defect in the transporter mediating the uptake of Isometamidium is not associated to neither the Alamar Blue phenotype nor Cymelarsan resistance.

8.3.3.2 Localisation of the reduced Alamar Blue dye in trypanosomes

When reduction of Alamar Blue takes place the dye transforms from a charged, non-fluorescent, blue compound to a non-charged, fluorescent, pink compound. To assess the localisation and potential concentration of the reduced Alamar Blue dye inside trypanosomes, procyclic forms of each pair of isogenic lines were incubated in the presence of the Alamar Blue dye and examined by fluorescence microscopy using a DAPI filter. Fluorescence microscopy showed the presence and accumulation of the reduced Alamar Blue dye in vesicular-like organelles (Figure 8.6). These organelles were distributed throughout the cell in both sensitive and resistant lines of 386 and 247. The fluorescent organelles can be observed almost immediately after mixing the dye with the trypanosomes. The morphological integrity of the trypanosomes was intact as assessed by phase contrast microscopy (Figure 8.6).

8.3.3.2 Endocytosis

The weak base chloroquine is a lysosomotropic agent known to reduce the acidity of endosomes and lysosomes (Krogstad *et al.*, 1985). Chloroquine has been used, in many organisms, to assess the uptake and degradation of material through the endocytic pathway and is thought to act by blocking the formation of the secondary lysosome. Studies on the

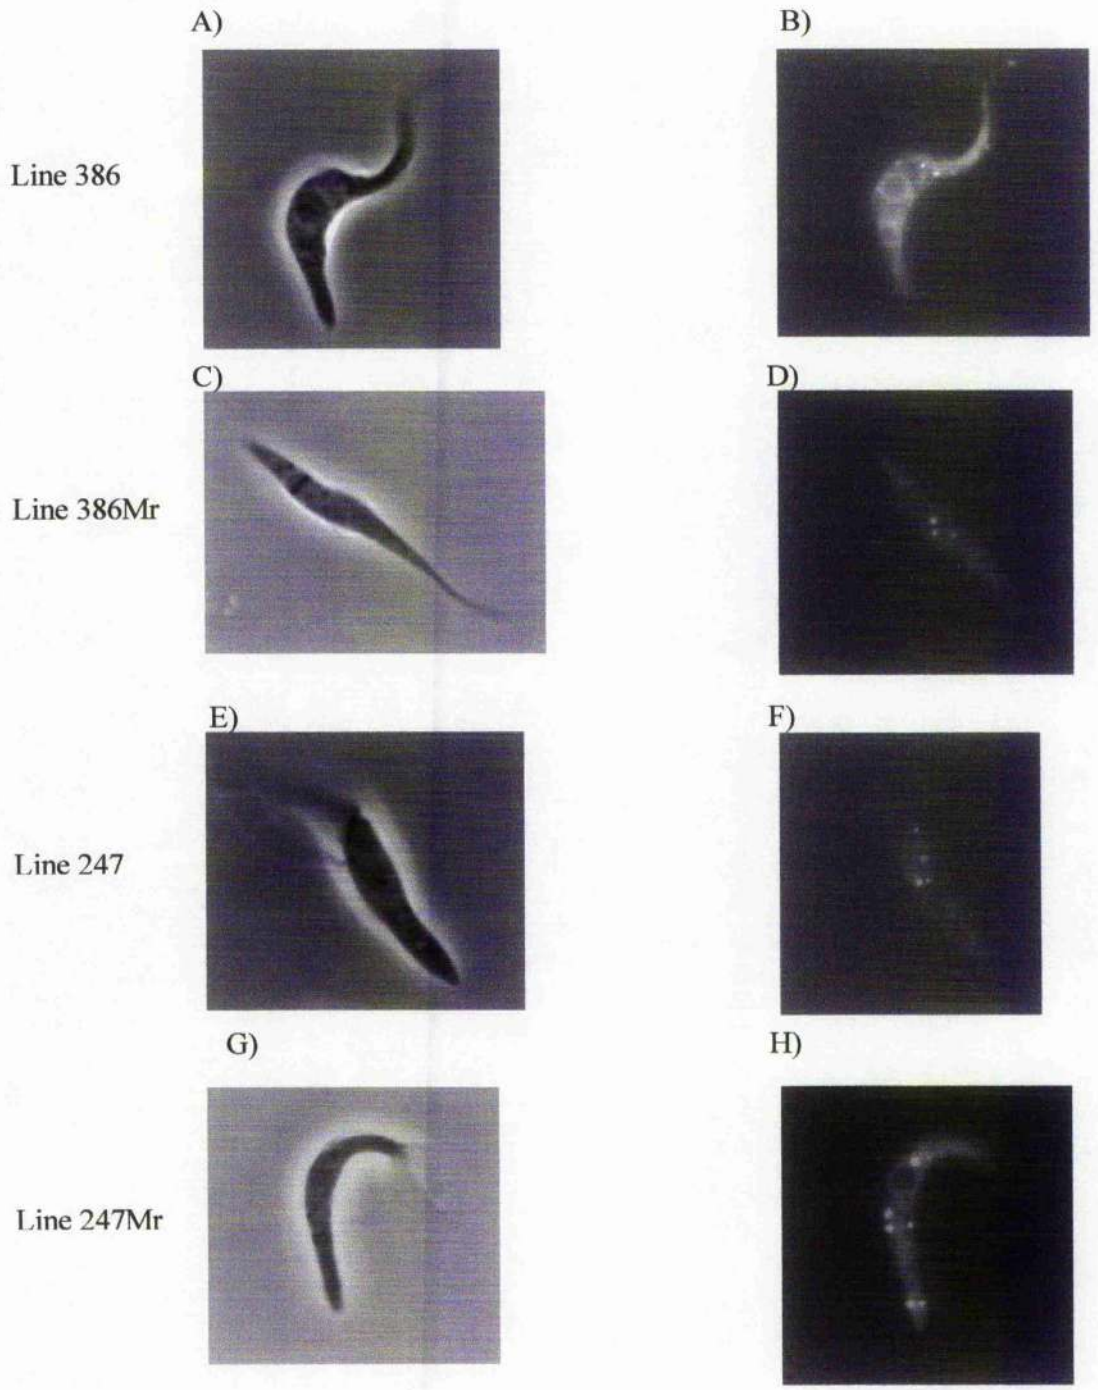

Figure 8.6: **Localisation of the Alamar Blue dye in the pairs of isogenic lines**. Phase contrast and fluorescence microscopy of trypanosomes after incubation in Alamar Blue showed the presence and concentration of the reduced Alamar Blue dye in vesicle like pockets inside the trypanosomes.

internalisation of HDL and anti-CRAM IgG by endocytosis, for example, revealed that exposure of procyclic trypanosomes to 50 μM of chloroquine completely abolished the lysosomal degradation of these molecules (Lee *et al.*, 1999; Liu *et al.*, 2000).

Chloroquine was used to determine whether the Alamar Blue dye was transported into trypanosomes via the endocytic pathway. The Alamar Blue assay was performed on procyclic stages of each pair of isogenic lines in concentrations of chloroquine up to 50 μM. A dose dependent decrease in the fluorescence from the Alamar Blue dye was observed for the sensitive lines and at a concentration of 50 μM of chloroquine, the fluorescence had dropped to a level similar to that produced by the Cymelarsan resistant lines (Figure 8.7A and 8.8A). The presence of chloroquine in the medium had no detectable effect on the fluorescence from the Alamar Blue dye produced by the Cymelarsan resistant lines.

Fluorescence microscopy performed on the procyclic forms of each pair of isogenic lines incubated in the presence of chloroquine and Alamar Blue showed the reduced dye in vesicle-like organelles in both sensitive and resistant lines (Figure 8.7C/E and 8.8C/E). These structures were distributed throughout the cell, as previously seen in the absence of chloroquine (Figure 8.6). The organelles appeared larger and more numerous in the trypanosomes incubated in the presence of chloroquine. The trypanosomes were intact as assessed by phase contrast microscopy (Figure 8.7B/D and 8.8B/D).

Chloroquine is believed to act on the endocytic pathway at the level of secondary lysosome formation by reducing the acidity of endosomes and lysosomes through the inhibition of the

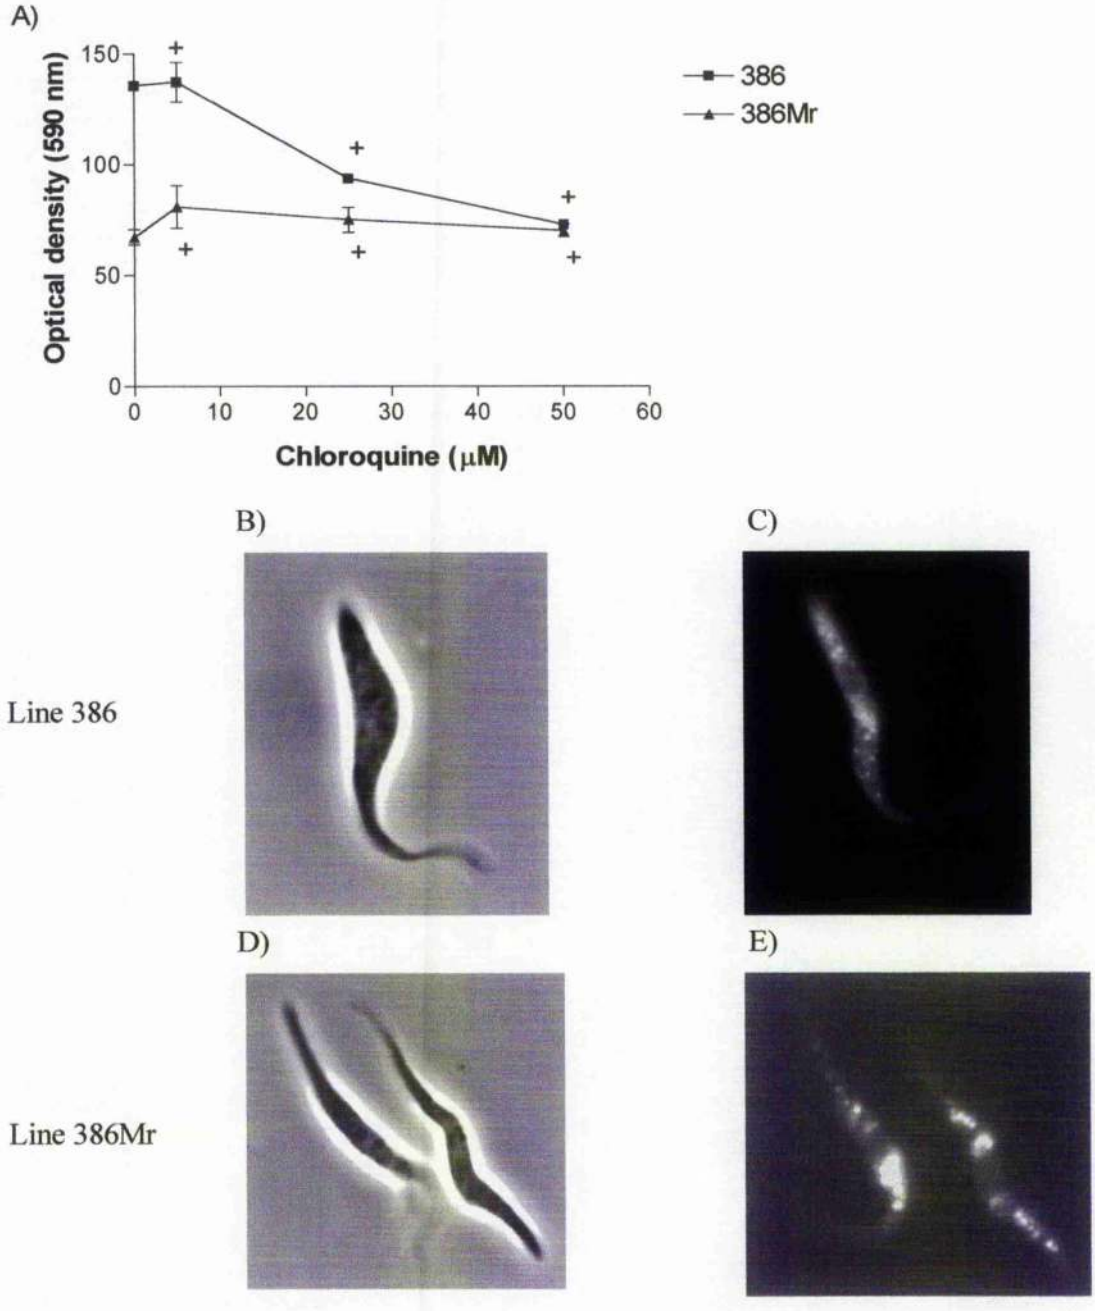

Figure 8.7: Alamar Blue assays of the isogenic 386 lines incubated in the presence of chloroquine (A). The status of the procyclic culture is indicated, for each concentration of drug, as alive (+) or dead (-) as assessed by microscopy. proton pumps present on these organelles. This in turn is thought to inhibit the formation of the secondary lysosomes. To assess whether the difference in the level of reduced Alamar Blue dye produced by Cymelarsan sensitive and resistant lines was due to a reduced acidification of endosomes and lysosomes, three known inhibitors of proton pumps were tested for their ability to decrease the level of reduced dye produced by the sensitive lines. Bafilomycin A1 and Concanamycin A are macrolide antibiotics know to specifically inhibit two types of proton pumps: V-ATPase at nM concentration and P-ATPases at mM concentration (Drose and Altendorf, 1997). The third inhibitor, ammonium chloride, is a weak base that has been shown to increase *Plasmodium falciparum* vesicles pH at concentration of 50 mM, in a similar way as chloroquine (Krogstad *et al.*, 1985).

Bafilomycin A1 (up to 3.2 μM), Concanamycin A (up to 29 μM) and ammonium chloride (up to 1 M) were used in the Alamar Blue assay on procyclic forms of each pair of isogenic lines to determine whether the reduced acidification of endosomes and lysosomes in trypanosomes was linked to the level of reduction of the Alamar Blue dye. Microscopic examination of the cultures after 24 h demonstrated that concentrations of 3.2 μM of Bafilomycin A1 and 1 M ammonium chloride were lethal to procyclic trypanosomes (Figure 8.9A/C and 8.10A/C). Sub-lethal concentrations of Bafilomycin A1 and ammonium chloride had no detectable effect on the level of reduced Alamar Blue dye produced by Cymelarsan sensitive and resistant lines. Similarly, Concanamycin A up to 29 μM had no effect on the level of reduced Alamar Blue dye produced by sensitive and resistant lines (Figure 8.9B and 8.10B).

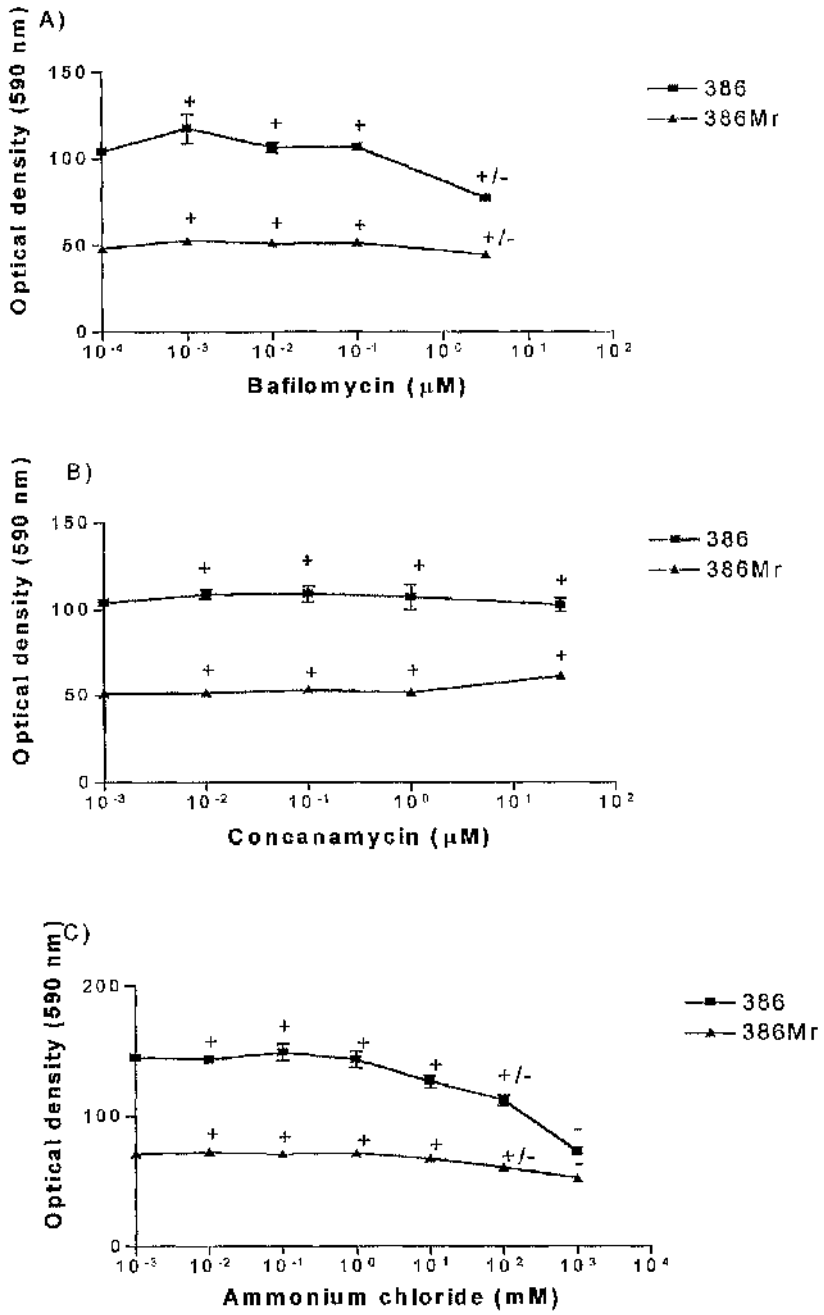

Figure 8.9: Alamar Blue assays of the isogenic 386 lines in the presence of lysosomotropic agents. Three lysosomotropic agents were tested (Bafilomycin A1 (A), Concanamycin A (B) and ammonium chloride (C)) *in vitro* in SDM79. The status of the culture is indicated as alive (+) or dead (-) as assessed by microscopy for each concentration of inhibitors. The lowest concentration corresponds to the control in the absence of drug. The error bars represent the mean +/- SEM, n = 4.

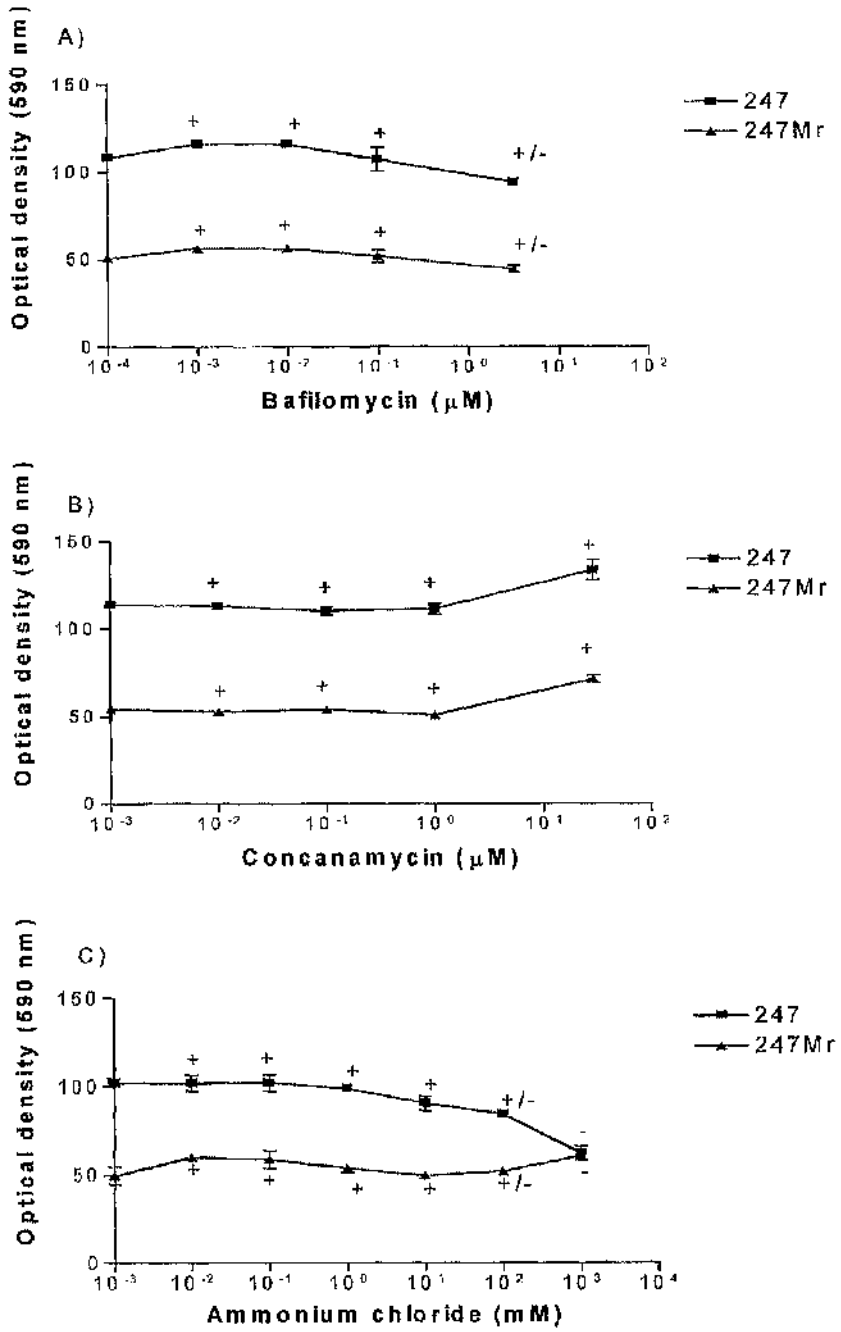

Figure 8.10: Alamar Blue assays of the isogenic 247 lines in the presence of lysosomotropic agents. Three lysosomotropic agents were tested (Bafilomycin A1 (A), Concanamycin A (B) and ammonium chloride (C)) *in vitro* in SDM79. The status of the procyclic culture is indicated as alive (+) or dead (-) as assessed by microscopy for each concentration of inhibitors. The lowest concentration corresponds to the control in the absence of drug. The error bars represent the mean +/- SEM, n = 4.

Taken together the results suggest that the reduction of the Alamar Blue dye is sensitive to the presence of chloroquine in the medium. However, the action of chloroquine on the production of the reduced Alamar Blue dye is not associated to its ability to decrease the acidity level of endosomes and lysosomes. The question arises as to the mode of action of chloroquine on the reduction of the Alamar Blue dye. One possibility is that chloroquine might inhibit the intracellular enzymes responsible for the reduction of the Alamar Blue dye. To test this hypothesis, an *in vitro* Alamar Blue assay was performed on cell lysates from sensitive and resistant lines of 386 and 247 in the presence of chloroquine (Figure 8.11). At a concentration of 50 μM of chloroquine the fluorescence has dropped slightly in both sensitive and resistant lines. However, the drop in fluorescence observed on cell lysates was lower that that observed for live trypanosomes. These results would suggest that the intracellular enzymes responsible for the reduction of the Alamar Blue dye are not inhibited by chloroquine.

Suramin has been reported to bind to serum proteins because it is negatively charged and enter the trypanosome via a LDL receptor mediated endocytosis (Vansterkenburg *et al.*, 1993). The Alamar Blue dye is also negatively charged and could potentially use an equivalent route of entry into trypanosomes. An *in vitro* Alamar Blue assay on procyclic trypanosomes incubated in the presence and the absence of serum however showed no detectable differences in level of fluorescence (Figure 8.12). These results suggest that the entry of the Alamar Blue dye into trypanosomes does not require binding to serum components.

8.3.3.4 The effect of Cymelarsan on the localisation of the reduced Alamar Blue dye in trypanosomes

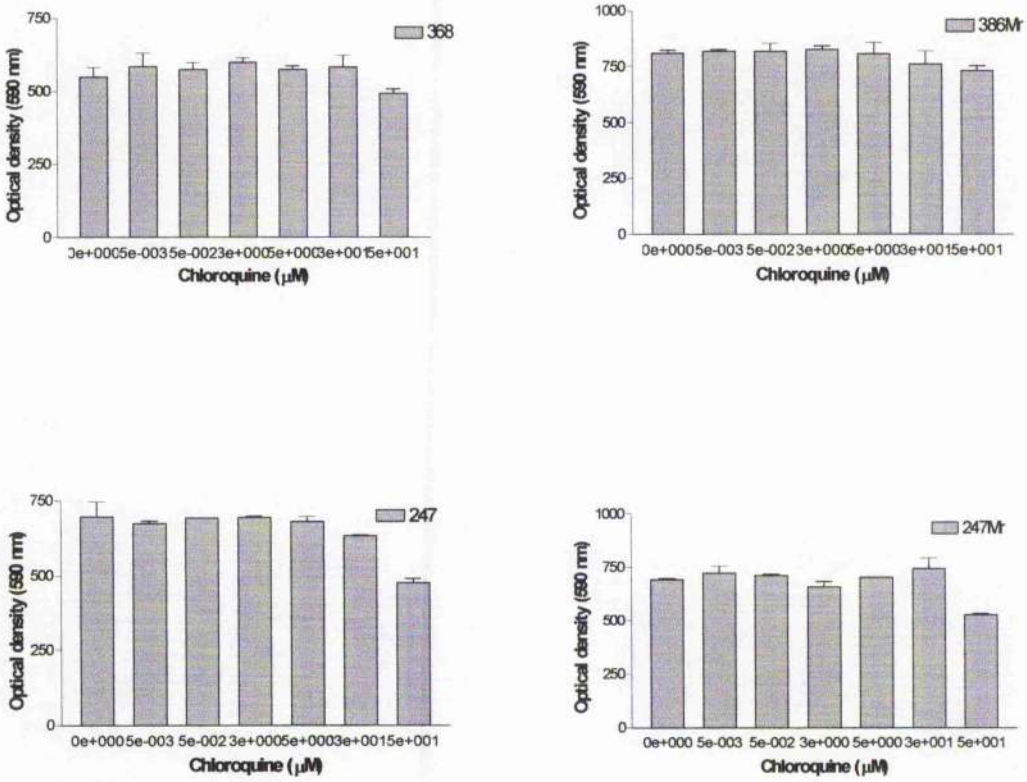

Figure 8.11: Alamar Blue assays on cell lysates in the presence of chloroquine. Chloroquine was added to cell lysates from each pair of isogenic lines to assess its effect on the intracellular enzymes responsible for the reduction of the Alamar Blue dye. The error bars represent the mean +/- SEM, n = 2.

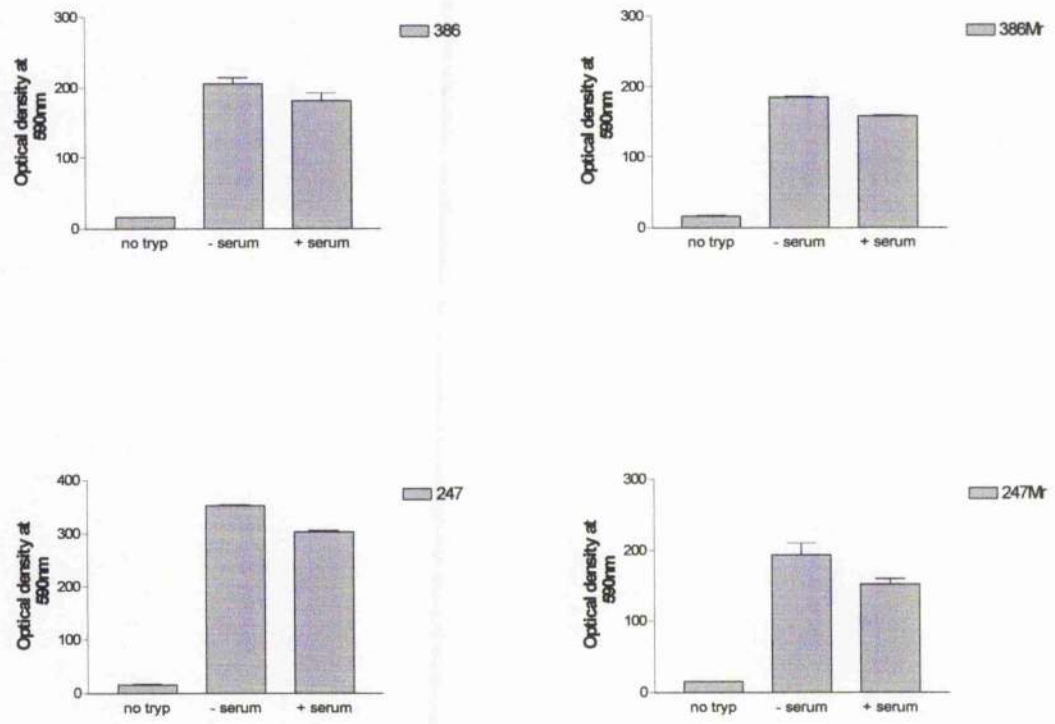

Figure 8.12: **Uptake of the Alamar Blue dye in the absence of serum**. Procyclic trypanosomes were incubated in Alamar Blue in the presence and absence of serum to test whether uptake occurred via binding to serum components. The error bars represent the mean +/- SEM, n = 2.

To assess whether Cymelarsan had an effect of the reduction and localisation of the Alamar Blue dye in the trypanosome cells, each pair of isogenic lines was incubated in the presence of Alamar Blue and observed by fluorescence microscopy using a DAPI filter prior to the addition of Cymelarsan. After addition of Cymelarsan the fluorescence from the vesicle-like structure disappears rapidly while the trypanosomes were still morphologically intact (Table 8.3). This phenomenon was observed for both sensitive and resistant lines, and suggests that the Cymelarsan might affect the membrane of the vesicle-like structures in a way that enables the fluorescent Alamar Blue dye to leak out.

8.4 Discussion

The Alamar Blue assay was developed by Räz *et al.* (1997) to assess the sensitivity of African trypanosomes to various drugs *in vitro*. The trypanocidal activity of drugs such as Melarsoprol, DFMO, Pentamidine and Suramin against *T. b. gambiense* (STIB 930) and *T. b. rhodesiense* (STIB 900) was shown to be readily assayed (Räz *et al.*, 1997). In the results presented here, assaying Cymelarsan sensitive and resistant lines showed an association of Cymelarsan resistance with a decreased production of reduced Alamar Blue dye. Two mechanisms by which the Cymelarsan resistant lines could produce less reduced Alamar Blue were assessed: a) the ability of cellular enzymes to reduce the Alamar Blue dye and b) the mode of transport/efflux of the Alamar Blue dye.

Line	Drug		Fluorescence microscopy	Phase contrast microscopy
386	Alamar Blue	_	Vesicles like structure	Intact
	Alamar Blue	Cymelarsan	None	Intact
386Mr	Alamar Blue	_	Vesicles like structure	Intact
	Alamar Blue	Cymelarsan	None	Intact
247	Alamar Blue	_	Vesicles like structure	Intact
	Alamar Blue	Cymelarsan	None	Intact
247Mr	Alamar Blue	_	Vesicles like structure	Intact
	Alamar Blue	Cymelarsan	None	Intact

Table 8.3: Fluorescence microscopy of each pair isogenic lines in the presence of Alamar Blue and Cymelarsan. The effect of Cymelarsan of the distribution of the reduced Alamar Blue dye inside the trypanosomes was assessed by fluorescence microscopy. The experiment was performed only once for each pair of isogenic lines.

The Alamar Blue assay is based on the ability of intra-cellular enzymes to reduce the non-fluorescent blue dye to a pink fluorescent compound. Cell lysate from sensitive and Cymelarsan resistant lines reduced the Alamar Blue dye *in vitro*. Many enzymes have been reported to be able to reduce the Alamar Blue dye *in vitro*. The list includes mitochondrial enzymes such as flavin mononucleotide dehydrogenase, flavin adenine dinucleotide dehydrogenase, nicotinamide adenine dinucleotide dehydrogenase, nicotinamide adenine phosphate dehydrogenase, dihydrolipoamine dehydrogenase, NAD(P)H:quinone oxidoreductase and cytochromes (Gonzalez and Tarloff, 2001). It would seem unlikely that all these enzymes could be altered in the Cymelarsan resistant line, and this is confirmed by the experiment carried out on the cell lysates.

The Alamar Blue assay is based on the fact that the dye can only be reduced by intra-cellular enzymes and therefore requires the uptake of the dye in order for it to be reduced to the fluorescent product, and then excreted into the medium (O'Brien *et al.*, 2000). The route of entry of Alamar Blue into the trypanosome is unknown. Uptake by the parasite can be the result of passive diffusion, receptor-mediated uptake, transporter-mediated uptake or endocytosis. The chemical structure of the oxidised Alamar Blue dye (Figure 8.1) would indicate that the molecule is unable to diffuse inside the cell due to its charged state so it is likely that a mode of transport is required. There are two possible modes of transport by which a compound can enter a trypanosome: through a transporter or via the endocytic pathway.

Comparison of the structure of the oxidised Alamar Blue dye with various trypanocial drugs revealed a structural similarity with Isometamidium. This structural similarity suggested that

the Isometamidium transporter was a possible transporter for the dye. Transport of Isometamidium occurred in both sensitive and Cymelarsan resistant lines and no increase in Isometamidium resistance was observed in the Cymelarsan resistant lines suggesting that the transport of Isometamidium was similar between the lines. This suggested that the Alamar Blue phenotype was not linked to Isometamidium uptake.

The identification of vesicle-like structures in which the reduced Alamar Blue dye accumulates inside the trypanosomes and the partial inhibition of the reduction of the dye in sensitive lines by 50 μM of chloroquine, suggested uptake via the endocytic pathway. Lysosomotropic agents are compounds which reduce the acidity of organelles in the endocytic/lysosomal pathways. Chloroquine is a lysosomotropic agent thought to act on the endocytic pathway (Figure 8.13) by increasing the pH of lysosomes preventing the formation of secondary lysosomes (Malik *et al.*, 2001; Blanchard *et al.*, 2000). The use of three other lysosomotropic agents (Bafilomycin A1, Concanamycin A and ammonium chloride) had no effect on the production of reduced Alamar Blue dye by Cymelarsan sensitive and resistant lines. This would suggest that acidic pH in lysosomes is not essential for the production of reduced Alamar Blue dye.

Studies on the internalisation by endocytosis of HDL and anti-CRAM IgG revealed that exposure of procyclic forms of trypanosomes to 50 μM of chloroquine completely abolished the lysosomal degradation of these molecules (Lee *et al.*, 1999; Liu *et al.*, 2000). The trypanocidal drug such as suramin can enter via the endocytic pathway bound to LDL (Coppens *et al.*, 1988; Vansterkenburgh *et al.*, 1993). The oxidised Alamar Blue dye is

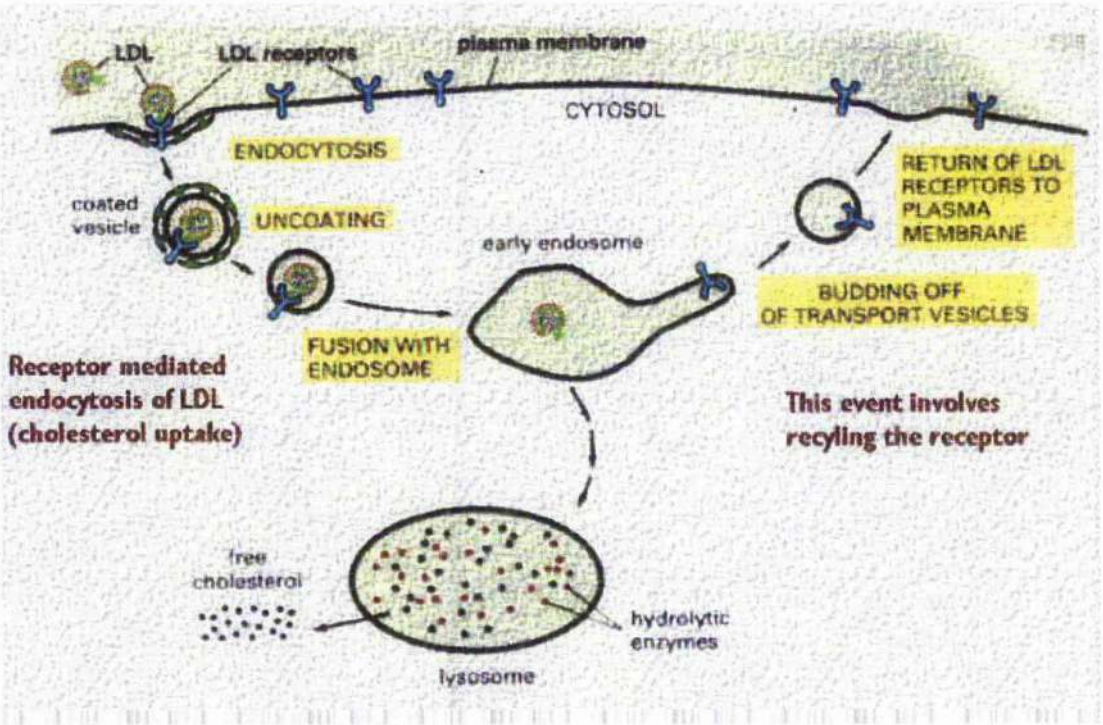

Figure 8.13: **Model of an endocytic uptake of LDL**. (Reproduced from http://cellbio.utmb.edu/cellbio/recend2.htm)

charged and could bind to HDL or LDL in the medium before internalisation via endocytosis. A preliminary experiment showed that Alamar Blue dye was still able to enter the trypanosome and be reduced in the absence of serum in the medium. This would suggest that the Alamar Blue dye enters the trypanosome via a different route. The elimination of the endocytic pathway as the route of entry of the Alamar Blue dye in the cell is further supported by the fact that procyclic trypanosomes show low levels of endocytosis (Langreth and Balber, 1975) and so it is difficult to account for the rapid appearance of the fluorescent vesicular-like organelles through this pathway. In addition, the vesicular-like structures accumulating the reduced Alamar Blue dye were located throughout the trypanosome cell, while endosomes and lysosomes are only observed around the flagellar pocket region (Langreth and Balber, 1975). Consequently the action of chloroquine on the reduction of the Alamar Blue dye appears to be unrelated to its ability to decrease the acidity of lysosomes. In addition, 50 μM of chloroquine had no inhibitory action of the cell lysate and so the mode of action of chloroquine on the production of the reduced Alamar Blue dye in the trypanosome has not been determined so far.

The vesicular-like structures accumulating the reduced Alamar Blue dye appeared to correspond to dense granules that are observed under phase contrast microscopy (Figure 8.14). The location of these vesicular-like structures and their appearance are characteristic of acidocalcisomes (Docampo and Moreno, 2001). In addition acidocalcisomes have been shown to swell in the presence of chloroquine (Coppens *et al.*, 1993) which would explain the larger fluorescent vesicles observed when trypanosomes are incubated in the presence of the Alamar Blue dye and chloroquine. Acidocalcisomes are acidic organelles described as cytoplasmic electron dense granules containing calcium, magnesium, sodium, zinc, iron and pyrophosphate

(Figure 8.15; Miranda *et al.*, 2000; Scott and Docampo, 1998; Rodrigues *et al.*, 1999). The low content of S found in these organelles would suggest that they have a low protein content. The function of these organelles is unknown although Docampo and Moreno recently (1999) have suggested four possible functions based on the information available: a) a role in the process of calcium storage, b) a role as an energy storage organelle containing large amount of pyrophosphate, c) a possible role in the regulation of cytoplasmic pH through the H^+ATPases present in the membrane and finally d) a role in the control of the process of osmoregulation. Analysis of the association between the lowered level of Alamar Blue reduction and Cymelarsan resistance in procyclic form of *T. brucei* has lead to the identification of vesicle-like structures that may be acidocalcisomes. The rapid disappearance of the fluorescence from the vesicles was observed after the addition of Cymelarsan to the medium. However the integrity of the dense granules was not influenced by the addition of Cymelarsan. The diverse functions suggested for acidocalcisomes clearly support the view that these are important organelles for the trypanosome. One hypothesis based on the results presented in this chapter, is that Cymelarsan could act on the membrane of the acidocalcisomes, rendering them leaky. This would explain the disappearance of the reduced Alamar Blue dye from the vesicles when trypanosomes are incubated in Cymelarsan, as well as suggesting a release of the acidocalcisomes' contents into the cytoplasm. The release of the contents of the acidocalcisome is likely to lead to a decrease cytosolic pH with a consequent inhibition of metabolic pathways. To test this hypothesis it would first be necessary to prove that the vesicular-like structures accumulating the Alamar Blue dye are acidocalcisomes and this could be undertaken by using acidocalcisome specific antibodies (Lemercier *et al.*, 2002) and Alamar Blue, in a co-localisation study.

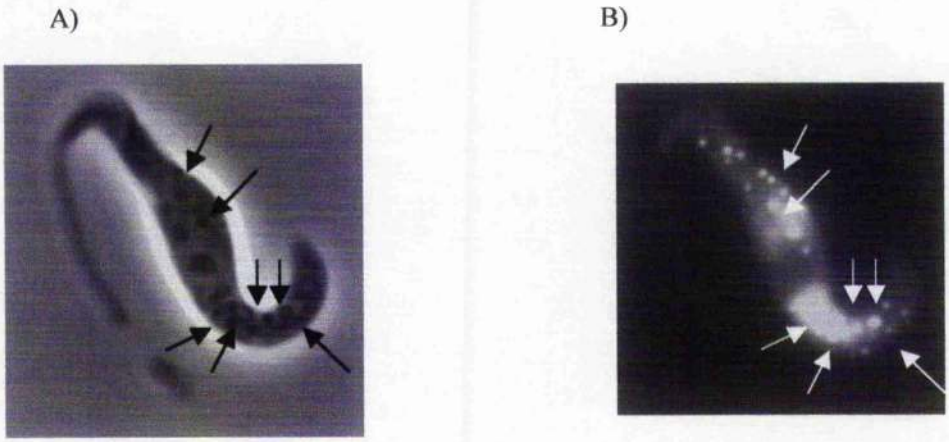

Figure 8.14: Localisation of the Alamar Blue dye in procyclic trypanosomes. Apparent co-localisation of the dense granules under phase contrast (A) and the vesicular-like organelles (B) accumulating the reduced Alamar Blue dye.

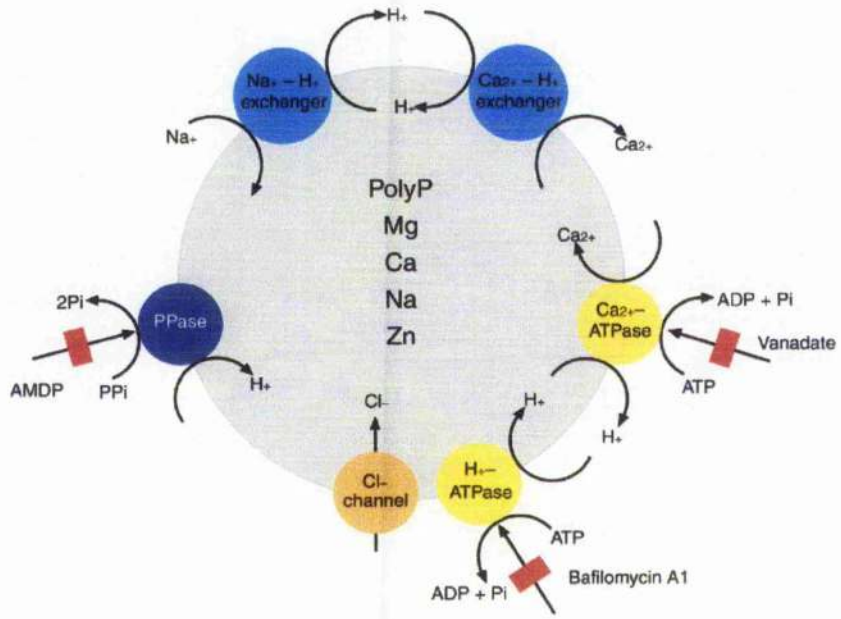

Figure 8.15: Model of an acidocalcisome in trypanosomes. Calcium ions uptake occurs in exchange for H^+ by a reaction catalysed by a vacuolar Ca^{2+}-ATPase which is inhibited by vanadate. A H^+ gradient is established by a Bafilomycin A1-sensitive vacuolar H^+-ATPase and an aminophenylethylenephosphonate (AMDP)-sensitive vacuolar H^+-Ppase. Chloride (Cl^-) transport, through a chloride channel is associated with the function of the vacuolar H^+-ATPase. Ca^{2+} release occurs in exchange for H^+ and is favored by sodium-proton exchange. The acidocalcisome is rich in pyrophosphate, magnesium, calcium, sodium and zinc. (Docampo and Morena, 2001).

To properly assess the function and involvement of the acidocalcisome in Cymelarsan resistance in *T. brucei* it would be necessary to study the membranes of acidocalcisomes. This would require the isolation of a sub-cellular fraction containing well-preserved acidocalcisomes and no other cell membranes. A method has recently been developed for the preparation of acidocalcisomes (Scott and Docampo, 2000). Measurements of the pH of a solution containing acidocalcisomes in the presence and absence of Cymelarsan would determine the effect of Cymelarsan on the membranes of acidocalcisomes.

Chapter IX
General discussion

The aim of this project was to investigate mechanisms of arsenical resistance in the protozoa parasite *T. brucei*. This aim was pursued by subtractive analysis of the whole protome from drug sensitive and resistant isogenic lines. It was anticipated that differentially expressed proteins between the isogenic lines would be associated with Cymelarsan resistance and could determine the mechanisms of arsenical resistance in *T. brucei*.

Most drug resistance studies performed so far on *T. brucei* have relied on biochemical, genetic or functional analysis of a candidate gene. The drawback of these approaches is the need for the pre-selection of a gene to analyse. The proteomic approach employed in this study enabled the global proteomic expression profiling of a drug sensitive *T. brucei* line and its laboratory-derived isogenic drug resistant line. The advantage of this approach is that all the possible mechanisms of arsenical resistance can potentially be analysed at once.

A recently published protocol for the solubilisation of proteins from *T. brucei* (van Deursen *et al.*, 2003) was developed for the study of Cymelarsan resistance in procyclic forms of the parasite. The protocol was simple, reproducible and extracted membrane proteins. The limitations of protein identification due to the limited *T. brucei* genome database were assessed with the production of a preliminary proteome map. Forty-two percent of the protein

spots separated by 2DE and analysed by PMF were identified. Only 30% of the protein spot not identified was due to the incomplete *T. brucei* genome database.

Two pairs of isogenic lines were used in this study. Preliminary characterisation demonstrated that the resistance phenotype was stable after passage in mice and cyclic transmission through tsetse flies (Scott *et al.*, 1996). In addition, both bloodstream and procyclic forms of the parasites were shown to express the resistance phenotype and cross-resistance in bloodstream forms between Melarsoprol and Melarsen oxide had been shown. Procyclic forms of the parasites were further characterised in this study. No cross-resistance was detectable to either Melarsoprol, Pentamidine or Berenil for both pairs of isogenic lines. This was consistent with the fact that no P2 transporter activity can be detected in procyclic forms (de Koning *et al.*, 2000) which rules out the involvement of the P2 transporter as the main mechanism of Cymelarsan resistance in procyclic forms of these lines. Another known mechanism of drug resistance in trypanosomes and other parasites involves the excretion of drugs via an over-expressed P-glycoprotein (Shahi *et al.*, 2002). This mechanism was assessed on both pairs of isogenic lines by growth inhibition assay in presence of general P-glycoprotein inhibitors. The presence of the inhibitors had no effect on the resistance to Cymelarsan. The P-glycoprotein inhibitor, verapamil, has been shown to reverse drug resistance in *T. cruzi* (Neal *et al.*, 1989) and *T. congolense* (Sutherland and Holmes, 1993), and consequently was expected to inhibit the P-glycoprotein from *T. brucei*. The other two P-glycoprotein inhibitors, TFP and PCP, have never been shown to be effective against P-glycoprotein from trypanosomes. The two obvious mechanism of drug resistance, the alteration of transport by the P2 transporter and the increased efflux by a P-glycoprotein, were tested and found to be not associated with arsenical

resistance in procyclic forms of the 386 and 247 lines. To identify protein associated with arsenical resistance a subtractive analysis of whole cell extract from sensitive and resistant lines was performed.

The subtractive analysis of the global expression profile of 386 and 386Mr lines enabled the detection of two protein spots whose lack of expression was associated with Cymelarsan resistance in the pair of isogenic lines of 386.

The differential expression of the CAR protein (spot 2) was reproducible over nine independent protein extractions separated on pH 4-7 gels and on one protein extraction separated on pH 4-5 gel. The CAR protein is adjacent on the 2D gel to a protein spot (spot 1) with similar molecular weight but more basic pI. Both the CAR protein and spot 1 from the proteins extracted from 386 and 386Mr were identified as products of either ORF 274 or 277. The presence of an extra form of the CAR protein in the 386 line could be explained by a mutation in either one of the ORFs, an absence of transcription of one of the two ORFs in the 386Mr line, or a post-translational modification of spot 1 which occurs only in line 386.

Analysis of the sequences obtained for the two genes from both 386 and 386Mr lines showed that ORF 274 and 277 from the 386 line were identical to their homologues in the 386Mr line. In addition, the predicted sequence of the transcript of ORF 274 was identical to the predicted sequence of the transcript of ORF 277. PCR on total cDNA from both lines demonstrated that both ORFs were transcribed in each line. These results suggested that the CAR protein was a post-translationally modified spot 1. The simplest way of regulating the activity of a protein is

by changing the number of protein molecules in the cell. This is generally achieved by regulating gene transcription, mRNA translation, or the rate of mRNA and protein turnover. A more rapid increase in protein activity can be achieved by post-translational modification. For example, activation of a kinase by protein phosphorylation is a hallmark of intracellular signalling cascades (Hunter, 1995). Post-translational regulation of the CAR protein could allow large amounts of the protein to be present in the cell in an "inactive" form.

The identity of spot 2 was confirmed by Western blot analysis using an antibody raised by DNA vaccination strategy against the expressed product of ORF 274. The number of isoforms present in each line was detected by Western blot analysis of 2D gels. In total, three isoforms were detected at pH 4.2, 34 kDa in the extract from the 386 line and only two isoforms at this location in the extract of 386Mr. The association of the absence of the CAR protein with Cymelarsan resistance was confirmed in independent extractions, and the identity of the protein was confirmed by mass spectrometry and Western blot analysis.

From these results the question arise as to whether the CAR protein is associated with Cymelarsan resistance in other *T. brucei* lines. Analysis of the pair of isogenic 247 lines showed that the CRA protein was not associated with Cymelarsan resistance in these lines. In addition, the analysis showed that only one isoform of the CAR protein could be detected in both 247 and 247Mr lines. Currently the antibody raised against the transcript of ORF 274 is being used for immuno-localisation of the CAR protein in *T. brucei* to extend our knowledge of its potential function.

Analysis of the amino acid sequence of the CAR protein showed the presence of a NAC domain and a UBA domain. The function of this protein in *T. brucei* is unknown. From the presence of the NAC and UBA domains, it seems highly likely that the protein is part of a multi-protein complex. Many cellular functions are performed not by individual proteins but by large multi-protein complexes. The analysis of complexes formed with the CAR protein could help on understanding of the function of the protein with respect to Cymelarsan resistance in *T. brucei*. This experiment could be performed by immuno-precipitation using the antibodies raised against the expressed product of ORF 274. Biochemical purification of complexes followed by mass spectrometry has enabled the identification of multi-protein complexes in other contexts (Neubauer *et al.*, 1997).

The second protein spot associated with cymelarsan resistance in the pair of isogenic lines of 386 was identified by mass spectrometry as an arginine kinase. Using the mass spectrometry analysis it was not possible to determine whether the protein spot was the transcript of ORF 243 or 242. However, the absence of a protein product from either one of the two ORFs (or both) at pH 5.8 on 2D gels was associated with Cymelarsan resistance.

The comparative proteomic analysis of Cymelarsan sensitive and resistant lines of 386 by 2DE enabled the direct comparison of expression of 1,000 proteins spots separated on 2D gels. It is estimated that the trypanosome genome contains approximately 8,000 genes based on sequence from chromosome I and II (Hall *et al.*, 2003; El-Sayed *et al.*, 2003) and while all the genes will not be expressed at the procyclic stages of culture, it is expected that many proteins were not separated or detected in this study. Consequently, the proteomic analysis performed

on the sensitive and resistant lines was biased towards highly abundant and soluble proteins. The limitation of spatial resolution, which causes spots to overlap on the 2D gel, was first reported in 1982 for albumin, for which what was considered a pure protein spot was further separated into additional components by using IPG strips of 0.01 pH/cm (Bjellqvist *et al.*, 1982). The use of narrow pH range had been shown to increase the separation and resolution of protein spots (Cohen *et al.*, 2002). The problem of spatial resolution on 2D gels was addressed in this study by using narrow pH range strips. The use of narrow pH IPG strips has enabled the detection of another differentially expressed protein spot between sensitive and resistant line of 386. However, even using narrow pH range strips, only the most abundant proteins were detected. In order to increase the proteomic analysis of sensitive and resistant 386 lines, the sample would have had to be pre-fractionated.

Only a few comparative proteomic analysis of disease/resistant cells/organisms with control cells/organisms have been published to date. Comparative proteomic analysis in these studies revealed only a small number of proteins differentially expressed between the two cells/organisms. There seems to be a general trend towards the identification of a higher number of differentially expressed proteins when using a quantitative proteomic approach. For example, the comparative analysis of p-53 deficient mice (a tumour suppressor gene) with control mice showed only 7 protein spots, out of 886 analysed by 2DE, were specific to the p53 deficient mice (Anaki *et al.*, 2000). Whereas, the comparative and quantitative proteomic study of a cancer cell line (T47D) and its antiestrogen-resistant derivative showed 38 protein spots differentially expressed (up- or down-regulated by a factor of more than 2) out of 2,500 spots analysed by 2DE (Huber *et al.*, 2003). Similarly, a quantitative and comparative

proteomic study of mouse-virulent and avirulent *Toxoplasma gondii* showed 35 protein spots, out of 300 spots analysed by 2DE, were up- or down-regulated between the two lines (Nischik *et al.*, 2001).

The resistance to Cymelarsan in this line was induced by prolonged exposure to sublethal doses of Cymelarsan, a treatment which is likely to be highly mutagenic and may induce changes in addition to drug resistance. Consequently, the results presented here will need to be confirmed using other methods. It will be difficult to confirm the association between the absence the CAR protein (isoform of spot 1) with arsenical resistance as most technologies available will remove all forms of the protein (knockout, RNAi) or examine transcript levels (micro-arrays) which are probably not involved.

The complete proteome analysis is limited by the technology. It is possible that other differentially expressed proteins between the sensitive and Cymelarsan resistant lines were not identified. Fluorescent two dimensional difference gel electrophoresis (DIGE) allows samples labeled with different dyes to be co-separated on the same gel, thereby eliminating the gel-to-gel variation (Beaumont *et al.*, 2001). This technique will be very useful in quantitative and comparative proteomic studies.

Synteny in coding regions and conservation of strand-switch regions are observed between several trypanosomatid parasites, suggesting an evolutionary pressure to conserve the close association of certain genes within clusters. This organisation suggests that clusters encode proteins involved in related cellular processes, requiring co-regulation or similar expression

level. ORF 274 and 277 are present in a cluster containing mainly putative ORFs with homology to enzymes and chaperonine. Of interest is the presence of the Ubiquitin conjugating E2 enzyme, containing a UBA domain and involved in the degradation of proteins by the ubiquitination pathway (Madura, 2002; Hoffman and Bucher, 1996). The CAR protein also contained a UBA domain thought to enable it to bind to ubiquitin and other proteins associated with the ubiquitination pathway (Wilkinson *et al.*, 2001). The presence of the E2 enzyme gene and ORF 274 and 277 in this cluster on chromosome IX, all containing UBA domain, would suggest the involvement of the expressed products of ORF 274 and 277 in the ubiquitination pathway. The mechanism of resistance to arsenical drugs could thus be linked perhaps to a higher turnover of proteins in the cell. Arsenical drugs are known to have a high affinity for intracellular thiols such as trypanothione and dihydropoamide plus several enzymes including trypanothione reductase (Fairlamb *et al.*, 1989), 6-phosphogluconate dehydrogenase (Hanau *et al.*, 1996) and glycerol-3 phosphate dehydrogenase (Denise *et al.*, 1999), all of which are essential for trypanosome survival. A higher turnover of these proteins, which might be the cellular targets of arsenicals, would enable the parasite to survive in the presence of the drug.

These proteomic analyses of sensitive and resistant line of 386 have demonstrated that the resistance phenotype was associated with the absence of an isoform of the CAR protein. Consequently, the mechanism of arsenical drug resistance in these lines might be due to the absence of a post-translationmal modification pathway.

The biochemical analysis of the two pairs of isogenic lines showed the association of the Cymelarsan resistance phenotype with a decrease fluorescence produced from the metabolism of the Alamar Blue dye. Further analysis of the metabolism of the Alamar blue dye demonstrated that the activity of the reductive enzymes were similar between sensitive and resistant lines. The reduced Alamar Blue dye was shown to concentrate into vesicle-like structure thought to be acidocalcisomes. The addition of Cymelarsan to the lines incubated on the presence of Alamar Blue demonstrated the disappearance of the fluorescence from the vesicle-like structure, suggesting that the drug might act on the membrane of the acidocalcisomes. Acidocalcisomes are acidic compartments containing pyrophosphate, magnesium, calcium, sodium and zinc (Docampo and Morena, 2001). An alteration of their membranes could release the high proton content into the cytoplasm, which would affect many metabolic pathways. A protocol has recently been developed for the extraction of pure acidocalcisomes (Scott and Docampo, 2000). These could be used to analyse the effect of Cymelarsan on the membrane of acidocalcisome, by measuring the pH of a solution prior and after the addition of Cymelarsan.

Proteomic methods are "hypothesis generating". Whilst the significance of the CAR protein and arginine kinase in Cymelarsan resistance in *T. brucei* line 386 remains to be established, this study has demonstrated the potential of proteomics to provide unexpected insights into molecular mechanisms by virtue of its ability to study protein expression in its entirety without pre-supposing a specific mechanism. It appears that the differential expression of the CAR protein represents a change in the level of post-translational modification of an existing gene

product which could not have been identified by the application of purely nucleic-acid based technologies.

Wilkins, M. R., Gasteiger, E., Sanchez, J.-C., Bairoch, A., and Hochstrasser, D. F. (1998). Two dimensional gel electrophoresis for proteome projects: the effects of protein hydrophobicity and copy number. *Electrophoresis*, **19**, 1501-1505.

Wilkinson, C. R., Seeger, M., Hartmann-Petersen, R., Stone, M., Wallace, M., Semple, C., and Gordon, C. (2001). Proteins containing the UBA domain are able to bind to multi-ubiquitin chains. *Nat.Cell Biol.* **3**, 939-943.

Yarlett, N., Goldberg, B., Nathan, H. C., Garofalo, J. and Bacchi, C. (1991). Differential sensitivity of *Trypanosoma brucei rhodesiense* isolates to *in vitro* lysis by arsenicals. *Exp.Parasitol.*, **72**, 205-215.

Yates, J. R., III, Speicher, S., Griffin, P. R., and Hunkapiller, T. (1993). Peptide mass maps: a highly informative approach to protein identification. *Anal.Biochem.* **214**, 397-408.

Zhang, M. Q. (2002). Computational prediction of eukaryotic protein-coding genes. *Nat.Rev.Genet.* **3**, 698-709.

Zhang, W. and Chait, B. T. (2000). ProFound: an expert system for protein identification using mass spectrometric peptide mapping information. *Anal.Chem.* **72**, 2482-2489.

Zhang, W. and Chait, B. T. (1995). Protein identification by database searcing: a Bayesian algorithm. http://prowl.rockefeller.edu/preprint/zhang/zhang-asms-1995.html.

Zhang, X., Lee, J., and Chasin, L. A. (2003). The effect of nonsense codons on splicing: a genomic analysis. *RNA.* **9**, 637-639.

Zhang, Z., Harrison, P., and Gerstein, M. (2002). Identification and analysis of over 2000 ribosomal protein pseudogenes in the human genome. *Genome Res.* **12**, 1466-1482.

Zomerdijk, J. C., Ouellette, M., ten Asbroek, A. L., Kieft, R., Bommer, A. M., Clayton, C. and Borst, P. (1990). The promoter for a variant surface glycoprotein gene expression site in *Trypanosoma brucei*. *EMBO J.* **9**, 2791-2801.

Values of peptide masses ($M+H^+$) entered for searching the NCBInr and *T. brucei* databases with the MASCOT® search engine. The underline masses correspond to the peptides matching onto a protein in the database.

Sample	Protein	Accession	Score	P	ppm	Coverage	Peptide	MW	pI	Modification

Results from the MASCOT searches in the NCBI and the local *T. brucei* database for all the samples analysed. The results highlighted in blue correspond to protein spots identified in the NCBI database while the results highlighted in yellow correspond to the protein spots identified in the local *T. brucei* database. The results non-highlighted correspond to protein spot matched in a database but the score was lower than the database score, and so the protein identification falls outside the 95% confidence limits. The molecular weight and pI given in the table correspond to the expected values from the protein sequences in the database.

Figure 1: Protein isoform versus gene family. Alignment of the protein sequences from ORF 775 and 774 of *T. brucei* encoding elongation 1α demonstrate high homology between different genes of the same family. The highlighted sequences correspond to the peptides identified by PMF.

Table 2: Detailed results from the MASCOT® search engine for spot 1, 2, 3, 4 and 5 for 247 and 247Mr lines.

Name	Old Accession number	New Accession number
CAR protein	Tryp9.0.000322-274	Tb09.211.0120
CAR protein	Tryp9.0.000322-277	Tb09.211.0130
Arginine kinase	ORF 342	Tb09.160.4560
Arginine kinase	ORF 343	Tb09.160.4570,AK1
Arginine kinase	ORF 345	Tb09.160.1590,AK1

Table 1: Update of accession numbers given by GeneDB (http://www.genedb.org/) for the CAR protein and arginine kinase, as searched on the 11/02/2004.

What we see depends mainly on what we look for.

John Lubbock
